EDITOR'S PREFACE

This volume has been planned to accomplish three major purposes. First, it is designed to meet the requirements of the serious investigator who wishes to acquaint himself with various topics in modern psychology which lie outside his field of special interest and competence. No encyclopedia can ever supplant the need for a study of primary references, of course; but there is great value in encyclopedic surveys which suggest leads for deeper study and which supply the necessary orientation. Particularly is this true if the preliminary orientation be written by those who have achieved distinction through contributions to special areas within the science of psychology. Secondly, the undergraduate and the graduate student often voice a desire for a book which may extend their acquaintance with topics mentioned in lectures or encountered in their reading. Owing to the exigencies of time, many important topics may receive only a passing reference in classes and seminars; hence this volume should be serviceable in the enrichment of various topics by initiating the student into an intensive exploration of the primary data. In addition, it furnishes a useful book in which the student can browse with pleasure and benefit. Thirdly, it is intended to emphasize some of the trends in contemporary psychology which seem to have supplanted much of the traditional material. Consequently, in the apportionment of space, it was considered to be a justifiable procedure to omit certain topics in order to allot space to others. To the expert psychologist, this method may seem to be cavalier and presumptuous, especially if his own specialty be omitted or underemphasized. By way of extenuation, the Editor pleads that a single-volume encyclopedia necessarily imposes restrictions upon problems of emphasis. A careful study of research literature and of topics of papers read in meetings of psychologists, however, lends support to the procedure of selection.

If it were possible to commence with a sentence definition of psychology which would satisfactorily delimit the field and which would

be accepted by all students of the science, the difficulties encountered by the editor of a handbook or an encyclopedia would be considerably easier, though less challenging and stimulating. The author of an introductory textbook on psychology, however, may well suggest that the entire volume is actually the definition or might even express the wish that a definition could be placed at the end, not the beginning, of the text. This disagreement about the precise denotation of *psychology*, nevertheless, is more of a problem in semantics than a real issue in contemporary psychology. Actually, all competent authorities now agree that psychology is the application of the scientific method to a study of behavior of living organisms. Let it be hastily added that most psychologists would insist upon having an opportunity to amend and to amplify this tentative definition. Furthermore, the modern psychologist takes the point of view that man is a biological organism in a social environment and that everything which makes him characteristically human is the result of learning. Hence the psychologist is inevitably concerned with the biological basis of behavior, with the facts regarding growth and development, and with all the complexities of the social setting which influence, and which are influenced by, man. That knowledge about such matters is valid only when it rests upon experiments is a truism regarding which few would disagree.

For centuries, psychology was a subdivision of philosophy. This period Ebbinghaus has referred to as "its long past." Only in comparatively recent decades has it emerged from "the mother of sciences" and achieved status as an independent field of knowledge in which the methods of the philosopher have little to contribute. These decades Ebbinghaus has called "its recent history." Within the short period of a scientific attack upon psychological problems, most psychologists would readily assent, more valid knowledge has been acquired than in all the centuries of philosophical reflection and speculation. Still, however, the field is not

ENCYCLOPEDIA
OF
PSYCHOLOGY

ADOLESCENCE.—Adolescence as a phenomenon among the young of all social classes is largely a product of modern culture and civilization. The great-grandparents of present-day adolescents finished their schooling by the age of twelve or thirteen, went to work shortly thereafter, married any time after sixteen, and were living an adult life by the age of eighteen. It is only recently that education has been extended and marriage delayed until a true period of adolescence has become an almost universal phenomenon in American life.

Adolescence extends, roughly, from 13 years of age till 21 for girls and from 15 till 21 for boys. It is initiated by a short period of puberty, but it continues for many years after the advent of sexual maturity. Adolescent boys and girls have physical, emotional, social, and moral characteristics that mark them off from either children or adults. Typical adolescent growth, reactions, behavior, and attitudes will be presented in an effort to characterize the period.

I. PHYSICAL GROWTH

A. Growth in Height and Weight: Growth in height is rapid just before and during the early years of adolescence. For boys, height increases at an accelerated rate from 12½ through 14½, with additional smaller gains until 18, when adult height is usually reached. The greatest increases in weight for boys (since early childhood) are between the ages of 13 and 16. The gain of these three years is slightly more than that for the preceding five. The growth rates for girls show similar developments, except that the curve for height rises most sharply between 10½ and 14, while that for weight shows maximum development between 11½ and 14½. An increased growth rate in height is, for both sexes, a phenomenon of preadolescence and early adolescence. For the boys the gains in weight continue throughout adolescence, but for the girls weight is almost complete at 16. During childhood the average girl is a bit shorter than the average boy, but between the ages of 11 and 14 she is taller. She is

also a bit lighter than the average boy until her eleventh year, but heavier from then on until 14½. During or after their fourteenth year, boys suddenly shoot up and achieve both a greater average height and weight.

When longitudinal records* are classified according to the period during which growth is most rapid, it appears that those children who grow tall soonest tend to be taller at all ages and to have a slightly greater final height than those for whom the period of maximum growth comes later. The corresponding differences in weight are even more marked than those in height.

Individual growth curves demonstrate great variability both in size at any one age and in growth rate among children and adolescents. Thus one girl may be as tall at 10 as another at 17. One boy may grow rapidly from the start of adolescence, increase his rate after 15, and be still growing at 17, while another boy grows very rapidly from 14 to 16 and then stops altogether. It is rare for two children to show identical curves.

B. Growth in Strength: The increase in muscular strength is easily observable in both boys and girls, though more especially in boys—perhaps because they use their muscles more and are greatly concerned about achieving adequate muscular development. Further differences in strength between the sexes arise from the characteristic proportions of boys and girls, which give boys better leverage because of their wider shoulders, longer arms, and bigger hands. Strength is often measured by the amount of pressure one can exert by gripping something with his hands. Longitudinal results for both boys and girls show that at all ages boys are superior to girls, and that as they grow older their superiority increases. At age 11 the difference in strength between boys and girls is almost 4 kilograms of pressure, but by 17½ it has increased to 20 kilograms.

One investigator has followed the develop-

* Records compiled by measuring the same children year after year.

ment of children through the adolescent years by measuring each year the speed with which they could run, the height to which they could jump, the distance to which they could throw a ball, and the width of their broad jump. In all four forms of exercise the boys made marked improvement, but the girls ran more slowly and could broad jump a shorter distance as they grew older. Their ability to throw a ball and to jump upwards increased a little. At 13 years the inferiority of the girls was, respectively, on the four tests, one-fourth of a second in the dash, one-half an inch in the upward jump, two inches in the broad jump, and forty feet in the ball throw; 3 years later it was one and one-half seconds, four and one-half inches, two feet, and seventy-two feet, respectively.

C. Skeletal Growth: Investigators have traced development of skeletal structure by taking X-ray pictures of the wrist, hand, or leg bones. At birth there is no difference between the sexes, but by the time girls are four years old they are already nearly a year ahead of boys in skeletal age. At eight, they are a year and a half in advance; during adolescence they are two years ahead. At fourteen, a girl's bones are almost mature, and at seventeen they are entirely so. In infancy the size of the bones is about the same for both sexes. During childhood it is slightly more for girls, but after the age of fourteen the boys' bones become progressively larger than those of the girls. At maturity both sexes have equal development as regards density and hardness.

The teeth also have characteristic growth rates. The permanent teeth begin pushing out the baby teeth when a child is 5 or 6 years of age. From that time on until the early years of adolescence a child acquires one or two teeth each year. The average 13-year old has 26 or 27 of his 32 teeth. As in all kinds of physical development, the girls are in advance of the boys; their teeth erupt earlier, and at all ages they have a larger number. The second molars usually erupt at the beginning of adolescence and the third molars—or wisdom teeth—at some time after 17 years of age.

D. Growth in Bodily Proportions: The parts of the body grow at different rates and reach their maximum development at different times. The head, for instance, does the major part of its growing before birth. On the other hand, the long bones in the arms and legs are ex-

tremely short at birth, remain comparatively short during childhood, and then lengthen quickly just before or during adolescence. The trunk is relatively long at birth, but it lengthens slowly during childhood, and attains its final length only as adulthood approaches. These variations in growth rate give the baby, the child, the adolescent, and the adult their characteristic proportions.

The face also grows rapidly in the early years of adolescence. The nose and mouth widen, and the forehead grows in both height and width. The upper part of the face usually develops faster than the lower, and the jaw is commonly the last feature to attain its adult size and angle. While some faces grow quite regularly, others show more or less disproportion during adolescence.

Changes in the bones, muscles, and proportions of the body are among the clearest indications of oncoming adolescence. When a boy starts cutting his second molars, when his chest grows deep, his shoulders broad, his hands and feet big, his arms and legs long, and his features large, he is clearly an adolescent. When a girl shows the same changes—though the shoulder and chest developments are less marked—and in addition reveals a widening of the hips and a tenderness in the breasts, she too has entered adolescence.

E. Growth in Circulatory, Respiratory, Digestive, and Nervous Systems: Changes in both the size and the tonus of the arteries are reflected in the measurements of blood pressure. From late childhood to late adolescence the blood pressure rises from 80 millimeters at age 6 to 115 at 18½ for boys, and 105 at 19 for girls. In the preadolescent and early adolescent years girls show a rise up to 120, followed by a reduction in the next two years; boys show a similar phenomenon, only it takes place three years later than among the girls. From childhood through adolescence the pulse rate becomes gradually slower. The heart drives the blood with greater force but it does not beat as often.

During adolescence the lungs grow, keeping pace with the increased width and depth of the chest. This development can be traced by measurement of lung capacity. At all ages the average boy is superior to the average girl, but in childhood and early adolescence the difference is not great. From the age of 14 on, however,

the curve for girls falls farther and farther below that for boys, although both continue to rise.

During adolescence the organs of digestion undergo considerable growth. The stomach becomes longer and increases in capacity. Because of the rapid growth rate in the size of the body, the adolescent needs more nourishment than formerly, and because of the enlarged capacity of the stomach, he craves more food. The net result is usually a tremendous appetite for three or four years.

The number of different fibers in the nervous system is complete at birth, but not all neural functions are present at that time. There is almost no increase in the length, width, capacity, or weight of the brain during adolescence, because the brain has achieved its adult size in childhood. What growth there is, then, is confined to further development of the fibers, in both length and thickness, and to further contacts among them. Evidence seems to show that the complexity of the brain—that is, the total number of contacts between fibers—is increased somewhat during the early years of adolescence.

F. Glandular Development: Each endocrine gland has its own growth rates. The thymus develops rapidly in childhood; at thirteen it is 220 per cent heavier than at birth and 120 per cent heavier than in adult life. The thyroid, parathyroids, and pituitary develop at a fairly regular rate from birth to maturity. The pineal gland grows rapidly and reaches 90 per cent of its adult weight before a child is ten years old. The adrenals lose weight during the first year of life and do not regain their size at birth until the middle years of adolescence; thereafter, they increase quickly to their adult weight. The sex glands develop hardly at all during childhood; the ovaries have grown to 40 per cent of their adult weight by the time a girl is twelve, but the testes are still only 10 per cent of their final size when a boy is fourteen. The ovaries accelerate in growth somewhat from twelve to seventeen, when they are half their final weight; they then achieve the remaining half of their growth in the next three years. The testes grow rapidly for one year between fourteen and fifteen and then slowly. At twenty they have not yet attained their adult weight, although they have already developed their adult function.

Basal metabolism is the rate at which an organism is functioning. It is regulated by the thyroid gland. If an individual were exactly average, his rate would be measured as zero. When his bodily processes are accelerated, his rate is plus 1 or more; when they are retarded, it is minus 1 or more. In the preadolescent period—ages eleven to thirteen for girls and twelve to fifteen for boys—the rate rises from the customary zero to plus 13 or plus 14 and then sinks again. The rise for the girls is two years in advance of that for the boys, but is identical otherwise. Since the thyroid gland regulates metabolism, this temporary fluctuation means that the gland is unusually active for a brief time, probably because it is affected by maturation of the sex glands.

The maturing of the sex glands is the most important single development of the adolescent years. The mere physical ability to produce offspring is not, however, nearly as significant at the moment as the added depths and nuances of emotional life that develop along with physical puberty. The first point for consideration is the age at which maturity takes place. For girls the age can be determined with fair accuracy as being the time of the first menstrual period. With boys the determination is more difficult and must usually be estimated from the appearance of secondary sexual characteristics. There is a wide variation in the age of maturity. For girls this variation is from nine to eighteen years of age; for boys it is two years less—from ten to seventeen. Very few girls have matured before the youngest boy, but during the years from twelve through fourteen there are distinctly more mature girls than mature boys of the same age.

The age of menstruation is related to height, weight, and skeletal age. Those who mature earliest are, from early childhood, taller, heavier, and more advanced in skeletal development than those who mature later. Among boys the advent of puberty seems to accelerate growth in both height and weight, but for most girls, the onset of menstruation marks the end rather than the beginning of rapid growth. A similar relationship exists between the age of the first menstrual period and the development of the bones. Those girls who menstruate before twelve and a half are nearer to skeletal maturity than those whose first period is between twelve and a half and thirteen and a half, and

this latter group is in turn superior to those who first menstruate after thirteen and a half.

II. EMOTIONAL DEVELOPMENT

Emotions do not seem to change much throughout life as far as the inner feeling and the bodily changes are concerned, but there are many changes in the stimuli that produce emotion and the overt reactions that are made to one's emotional state. To illustrate the nature of these developments, with special stress upon the stimuli and reactions typical of adolescence, the three emotions about which most is known have been selected for study.

The first of these emotions is anger, which has been studied from early childhood to late adolescence. Small children become angry because someone tries to take a plaything away from them, because of some conflict arising over getting dressed and going to the toilet, or because of some interruption of their activities by others. For adolescents of both sexes the commonest causes of anger may be described as "social," especially for girls. In addition, boys become angry over the failure of some material object to function properly. The remaining causes of anger listed by the adolescents are of an impersonal nature, such as anger at the weather, at being hungry and not having time to eat, at having a headache on the day of an important examination, and so on. The reactions made when one is angry also show a development with age. The small baby screams and beats the air with his arms and legs. The preschool child also cries, screams, and becomes stiff; in addition, he kicks, strikes, bites, scratches, stamps his feet, jumps up and down, or throws himself on the floor. To a slight extent he scolds and talks back. By adolescence the response of talking has become by far the most important. Actual violence is reported in few instances, although there is frequent reference to the suppression of such behavior. Instead, the boy or girl tends to substitute the reactions of pacing the room, going out for a walk, or indulging in some violent exercise as a means of working off the emotion. Finally, there is a persistence of infantile behavior in the form of stamping the feet or kicking things, on the part of the boys, and of crying, on the part of the girls. It should also be noted that the younger the individual the more immediate is the release of emotional tension. The dura-

tion of the anger also varies with the age of the individual. In the case of preschool children, anger lasts less than five minutes in 90 per cent of the cases. For college students the average period is fifteen minutes, and the total range varies from one minute to forty-eight hours.

The second emotion to be considered is fear. The common causes of fear, anxiety, or worry among children are: failing a test in school, father or mother being sick, father or mother working too hard, getting a bad report card, father losing his job, being late to school, being hurt by knives, guns, poison, fire, floods, or in an accident, holdup, burglary, or fight, being sick, suffering, choking, dying, losing money during an errand, losing one's fountain pen, losing one's friends.

High school pupils continue to show a few of the typical childhood fears, but new sources of worry appear. Adolescents concentrate upon fear of school examinations, automobile accidents, and disease; worry over inadequate funds, getting a job, loss of work by parents, or the appearance of the home; fear of being sinful, being led astray by bad companions, or being tempted to cheat; worry over being unsuccessful, over hurting other people's feelings, over making a bad impression upon others; fear of growing up, of social incompetence, of sexual experiences, of disappointing one's parents. It may be noticed that adolescent worries have their roots in social situations and are less numerous than those typical of childhood.

The reactions to fear are not varied. First there is a rigidity of the entire body and then a running-away. As children grow older and their intellectual abilities mature, they learn to do their running away before the stimulus appears; that is, they learn to avoid situations that may cause anxiety.

The third emotion to be presented is love. In psychological literature the person or thing that inspires the emotion of love has been termed the "love object." The love-objects that are most powerful vary with age, just as do the situations arousing either fear or anger. The first love-object for babies of either sex is undoubtedly the mother or the person who looks after them. Later on, the mother may be displaced by the father, by other adults, or—after school age—by a particular teacher. This fixation upon adults, often adults of the opposite

sex, continues normally until the middle years of childhood. Then, for a few years, children are usually more deeply attached to some other child of their own age and sex than they are to anyone else. These attachments are perfectly normal and are a necessary step in the gradual emancipation of a child from the emotional ties which bind him to his home. The period of devotion of boys to boys and girls to girls continues, usually becoming more intense, up to the years of adolescence.

The third and adolescent stage begins as soon as boys and girls select as a love-object an individual of approximately the same age but of the opposite sex. Usually the transfer from friends of one's own to members of the opposite sex is easy and natural. All that seems to be needed is the presence in the environment of a large number of possible love-objects. During the early and middle years of adolescence the constant falling in and out of love is entirely normal. By having many short periods of attachment to many different people, boys and girls gradually learn what kind of individual they really like best. Toward the end of adolescence or early in adult life there should be a narrowing of the field to one person of the opposite sex and of approximately the same age. Out of possible love-stimuli the young man or woman selects one as a permanent mate.

Within the past few years several investigators have worked out tests for measuring emotional maturity through the measurement of attitudes and interests. The results are expressed in terms of "emotional age," a concept exactly paralleling that of "mental age." An individual adolescent may be developing normally—that is, reacting to the usual stimuli for his age and sex—or he may be retarded emotionally—that is, he reacts to childish stimuli in a childish way—or he may be accelerated emotionally—that is, he responds only to adult stimuli and in an adult manner. People vary just as much in the rate of emotional as in the rate of physical growth.

III. SOCIAL DEVELOPMENTS

The adolescent years are, pre-eminently, a period of social development and adjustment. During these years, the boy or girl becomes acutely aware of social pressures and relationships. It is this sensitivity that leads the adolescent into the characteristic conformity of the

period. He wants to have the same kind of clothes, to use the same slang expressions, to do the same things, to study the same subjects in school, and to enjoy the same forms of amusement as his friends. Release from this social bondage to one's age-mates is achieved only slowly as the adolescent approaches adulthood.

A. Spontaneous Social Life: The typical social group during the adolescent years is the "crowd," which appears to be a tightly knit group of 6 to 10 or 12. The number of boys and girls is by preference exactly equal. The activities of these groups are difficult to list because the crowd seems to do practically nothing. In the summer it sits around on someone's porch, talks for hours, and makes occasional excursions to the neighborhood drugstore. In the winter it sits around in someone's house, plays the radio, and raids the icebox. None of this activity comes under the heading of adventure as seen through the eyes of childhood, but it is apparently exciting for the adolescent. It is adventure, not into the world of things but into the world of social relationships. It gives the participants an opportunity to develop their conversational powers and social skills on other people whose abilities are no better than their own.

The values obtained from such a crowd may be listed as follows: experience in getting along with other people, experience in social skills, development of loyalty to a group, practice in judging people, discovery of what they can and cannot do in the way of leadership, and experience in love-making under circumstances in which the participants are protected from serious consequences. The only negative training is the development of antagonism toward other crowds than that to which the individual belongs. For the most part, however, the crowd is a socially valuable unit of adolescent society and probably does more to bring about normal social growth than teachers and parents combined.

Normally, boys and girls develop many friendships with each other during the period of adolescence. These friendships are essential to normal adjustment. Nothing that results from them could possibly be as serious as their failure to develop. Aside from the emotional maturity reflected by the interest of boys and girls in each other, these friendships serve to give experience in courtship and to provide the

basis for subsequent ideals of mating and marriage. Far from being dangerous, the somewhat sentimental boy-and-girl attachments are highly educative at the time and are essential for self-protection in the years after home supervision has been left behind.

Both boys and girls show a definite evolution in their concepts of what constitutes desirable behavior. The preadolescent girl tends to idealize reactions that conform to the demands of adults—obedience, demureness, and docility. In early adolescence she exhibits behavior suggestive of an emotional disorganization: she makes exaggerated responses to stimuli—giggling over nothing, raving about this or that, and getting into moods of black despair. She has also a great interest in her own person and appearance. This stage is mercifully short, and presently—at about fifteen—the girls begins to put great value upon the typical boyish traits of activity and general noisiness. This stage also passes, and girls of sixteen are already accepting adult feminine patterns of behavior. Boys have a somewhat less complicated evolution of conduct. The twelve-year-old tries to emulate the hero who is daring, good at games, and a leader. He admires defiance of adult authority and regards neatness or obedience as signs of weakness. By fifteen he has changed somewhat. He still gets prestige from skill in games, and he admires aggressiveness and fearlessness; but he thinks defiance is immature and childish.

B. Homes for Adolescents: One major objective to be reached by the end of the adolescent period is the emancipation of the boy or girl from home control and from intense parental attachment. Between the ages of twelve and twenty an individual must change from a child who is dependent upon his home to an adult who is sufficiently detached from his parents to be able to establish a successful home of his own. The first need, then, in a home for those of adolescent age is a wise relinquishing of the strict control necessary for children and a wise development of adequate self-control in the adolescents themselves.

As children approach adolescence it is highly desirable that they be given an allowance, the amount of which is gradually increased so that from year to year they buy an increasingly greater proportion of what they need. Naturally, some of the expenditures will be unwise, especially at first. However, one can learn to spend

money wisely and appropriately only by actually spending it.

An adolescent should choose his own friends. Naturally, he will make some undesirable acquaintances, but no serious harm is likely to come about unless the parents, by an unpromising attitude, drive the adolescent out of his own home and force him to meet these undesirable individuals secretly. As in the case of spending money, a shifting of control from parent to child cannot take place overnight; but take place it must, sooner or later.

An adolescent needs a home in which the parents do not pass on to him their own maladjustments. Such conflict may be seen in its simplest form in the immigrant home, in which the parents are attempting to maintain their native customs in the face of American social forces. Many parents force their adolescent children to make decisions on exactly the same problems for which they themselves can find no solution.

A desirable home for adolescents offers them security. To be sure, the adolescent often goes along for weeks at a time without requiring other security than food and shelter, but when he gets into difficulties he needs a harmonious and sympathetic home quite as much as a small child does. As his independence increases, he falls back upon his home less and less frequently, but until he has set up a home of his own—and sometimes even later—there are sure to be occasions when he needs security above everything else.

As youngsters grow into adolescence parents should change the nature of the relationship between themselves and their children. The adolescent should emerge from the parent-and-child relationship and should gradually enter into the relationship of older and younger friends. This change will not often be made unless the parents take the initiative. Whether they intend to or not, parents serve as models, good or bad. From them and their attitudes toward each other a boy or girl gets his or her notions about home and life and marriage.

The desirable home for adolescent boys and girls has thus four characteristics: first, it allows its children to grow up; second, it does not pass on to them its own maladjustments to modern society; third, it provides a haven of emotional security in times of stress; and fourth, it serves as a model of what a home should be.

IV. MORAL DEVELOPMENT

This section will be short because relatively little research in this field has been done. Such data as are available will be presented under the headings of attitudes toward religion, growth in moral behavior, development of ideals, and need for a philosophy of life.

A. Attitudes toward Religion: For the most part, young adolescents accept whatever religious beliefs they have been taught, but even as early as the age of thirteen there may be some degree of doubt. The idea, popular in childhood, that one can get things by prayer has been largely outgrown, a few children are already questioning God's existence, and a considerable number have lost their confidence in God's omniscience and protection. The attitudes of older adolescents upon similar topics show in general an increased skepticism, although there are few who go so far as to become atheists. Church affiliation reduces the degree of skepticism and favors the acceptance of religious beliefs.

Various factors are more or less related to the development of religious beliefs. The relationship between chronological age and religious beliefs is negative. Girls usually revolt against accepted beliefs less frequently than boys, less profoundly, and at a later age. The correlation between the educational and economic level of homes and the acceptance of religious beliefs is also negative; that between belief and intelligence is either slightly negative or close to zero. The relation between acceptance of religious dogmas and religious observances in the home or attendance of the entire family at church is relatively high. With religious education or knowledge of the Bible there is no relation whatever.

As a teacher of ethics, the average church has undeniably lost ground within the last three generations, but it is still a dominant influence, even though church attendance decreases somewhat with age. At sixteen, 60 per cent of the boys and 65 per cent of the girls go to church once a week; only 11 per cent of the boys and 9 per cent of the girls never go. At twenty, one-fourth of the young men and over a third of the young women still go to church every week, while half the men and something over a third of the women attend church sometimes. No organization that has contacts with such a large

per cent of boys and girls from sixteen to twenty is a negligible factor in their lives.

B. Honesty: There has been a good deal of research into the actual behavior of children, in or out of school, as they reacted to situations in which they could be dishonest without apparent danger of being caught. Throughout childhood and early adolescence, a teacher can expect cheating in schoolwork from many pupils of average ability, from most dull pupils, and even from a few of the brightest children. In athletic contests and parties she is likely to observe dishonest behavior in some per cent between 30 and 50 of the pupils, without much respect to intelligence. She can expect greater dishonesty from retarded than from accelerated pupils and more from those who do poor work than from those whose work is satisfactory. If a given pupil's friends or siblings are known to be deceitful, she can anticipate dishonesty from the pupil concerned. She can also presume dishonest behavior in proportion to the amount of direct training in the particular situation being tested. Thus in a group of children of whom 80 per cent will peek through their fingers in order to trace a drawing more accurately, not more than 30 per cent will cheat in scoring their own papers, and not more than 3 per cent will steal money.

Cheating in schoolwork does not appreciably decrease as the pupils grow older, perhaps because there is always a group of pupils at the bottom of the class, no matter how much elimination has already taken place and the pressure upon them becomes greater with the passage of years. Failure in school is distressing enough to children, but it often means to the adolescent boy or girl a collapse of social as well as academic standing.

C. Development of Ideals: Since concepts grow out of experiences, the child with socially acceptable habits usually grows up into the adolescent with socially acceptable ideals. To be sure, the period of adolescence brings new experiences, and these will, in turn, lead to modifications. However, the essential connection between childhood experiences and adolescent ideals should not be forgotten. All ideals are generalizations of past experiences, used for the purpose of assaying present or future conduct.

Every normal adolescent has ideals, and he judges conduct in terms of them. It should not,

however, be supposed that all ideals are socially acceptable. The boy who sees in many diverse situations the ability of the strong to coerce the weak may develop the ideal that "might makes right." Such ideals have recently been developed much too completely by the youth of Europe. After developing this ideal, an adolescent may use it to guide his own conduct or as a basis for judging new situations. His generalization is just as truly an "ideal" as a conviction that the strong should protect the weak.

D. *A Philosophy of Life*: The modern adolescent wants to find a meaning to life, a synthesis of its discordant values, but certain elements in modern life make this effort especially difficult. First, he has from infancy been brought up on an objective, unemotional presentation of scientific facts. He usually knows just enough about science to block his acceptance of traditional religion but not enough to evolve a synthesis of science with religious and moral beliefs. Second, he is acquainted with many people, many customs, and many points of view. Third, he is met on all sides with the most divergent adult opinions. He sees no single, accepted mode of life, and he does not know what will satisfy his notions of right and wrong. Finally, he and his friends have extraordinary freedom from adult control. It is not surprising that the world seems chaotic and meaningless. Some adolescents find consolation in organized religion, but more of them have to work out their own salvation.

Young people want chiefly two things from their philosophy—a feeling of security that a rapidly changing society does not give them and an emotional satisfaction that is not provided by the scientific world around them. Modern science feeds the mind but not the imagination or the emotions. In their efforts to interpret the world so that it has a meaning for them, adolescents want not only a sense of personal security but also a stimulus to imagination and an opportunity for emotional thrill. In the course of time modern youth may work out a new synthesis of values that will almost certainly be independent of organized religion but probably will be an evaluation of human life in criteria that are social and ethical.

V. INTELLECTUAL GROWTH

Since the very earliest studies of adolescence, stress has been placed upon the characteristic

intellectual developments of the period. In life situations if not in test situations, there seems to be an increase in judgment, reasoning, comprehension, speed of performance, memory, concentration, or other mental functions.

A. *Growth Rates*: When one plots a curve for the mental growth of boys and girls who are re-examined yearly from early childhood to late adolescence, the curves are very nearly straight lines, the growth for all yearly intervals being almost equal. Children develop intellectually at a rate that is directly proportional to their initial capacity. The brighter a child is when he enters school the faster he will develop mentally, and the duller he is the slower he grows. As a result the bright and the dull become more and more unlike as they grow older, because the distance between them increases.

Specific tests show increases with age in various specific abilities. For instance, adolescent memory is better than that of childhood. This growth may, however, be obscured by a distaste for monotony, but if the material to be memorized is so presented as to seem a logical step in gaining a desired end, an adolescent can learn it more rapidly than a child. Ability to obtain insights, to judge, or to think increases by leaps and bounds during adolescence. Thus, the inadequate childish understanding of the parables in the New Testament shows a large increase between the ages of eleven and fourteen for the easier parables, and between eleven and eighteen for the harder ones. A similar rise is shown in the ability to interpret cartoons. There is some evidence of increases in imaginative power and in ability to concentrate.

B. *Growth in Interests*: During the adolescent years both boys and girls show characteristic developments in their interests in radio, movies, games, and reading.

Pupils above the primary grades listen to the radio from one to three hours per day. Boys at all ages like comedy best, then dance music, drama, and detective stories. Girls put drama first and comedy second, followed by specifically children's programs and dance music. Two-thirds of the children do other things while listening; they read, study, eat, play, or sew. Interest in dance music shows a considerable increase with age, while interest in children's programs declines. Children of all ages listen more or less to all kinds of programs,

their choice being apparently more influenced by the hour of a program than by its nature. In general, school pupils rate their interest in radio just behind their liking for the movies, ahead of their interest in the "funnies," and a good deal higher than their desire to read books.

Children like the same action and adventure in the movies that appeal to them in books. They are devoted to serials and love animated cartoons. At or even before puberty, girls begin to want love stories, and they soon develop a penchant for almost any story in which the scene is laid in a sumptuous house and the women wear lovely clothes. Boys are slower to forsake Western and gangster films, but eventually they too prefer love stories. Adolescent members of both sexes like humor—especially of the wisecracking variety, best typified by Charlie McCarthy—musical shows, and dancing. Newsreels are well liked by adolescents.

Perhaps the best way to see what effect movies have upon adolescents is to let them speak for themselves. Pupils report that they obtained help from the movies in selecting clothes, acquiring acceptable manners, developing better social adjustments, selecting love-making techniques, acquiring a philosophy of life, getting a better idea of modern society, developing ambition, realizing the value of family affection and loyalty, and developing religious and moral attitudes. Movies led them also into such emotional experiences as day-dreaming, terror, sorrow, romantic love, passionate love, grief, pathos, general tenseness and excitement, longing to be "good," and resentment at social discrimination or at family interference with adolescent ambitions. Adolescents may find dissatisfaction with their daily lives after observing life seen against a setting of luxury and freedom, and this dissatisfaction may take an acute expression in some form of rebellion against parental restraint. On the positive side, many high-school pupils develop a desire for travel and for further education, as a result of their attendance at the movies. In short, each adolescent finds in the movies the things he or she is interested in—excitement, romance, escape, knowledge, or training in social competence.

The three-year-old boy plays mostly alone and amuses himself with simple objects. The five-year-old plays with a ball and runs about in

active but unorganized games, such as tag. The older boy spins tops, plays marbles, or flies a kite. He also plays loosely-organized group games that are elementary forms of those so popular in later years. The pre-adolescent boy usually prefers hiking, camping, and swimming to competitive games. In early and middle adolescence, the favorite activities are highly organized group games, played with established rules. By the age of twenty-one interest in games has become more passive than active, and already the average boy has begun to develop the attitude of the average man, who derives pleasure from watching sports rather than from active participation in them.

Among girls there are parallel developments. The little girl begins, as her brother does, by playing alone at such simple amusement as banging a pan with a spoon. By six, however, differences in interest between the sexes have begun to show. The six-year-old plays with her doll and also likes such group games as London Bridge, Farmer-in-the-Dell, or Drop-the-Handkerchief. The nine-year-old likes paper dolls and doll-houses; she serves "afternoon tea," she likes to "dress up," and she plays many active games such as run-sheep-run, or hare-and-hounds. At twelve her amusements are more like a boy's than they are earlier. Swimming, roller skating, and hiking are especially popular; so also is reading. By the age of fifteen practically all athletics are popular, and the average girl is more active in her amusements than she ever is again. Dances and parties vie with athletics, however. The eighteen-year-old is strongly social in her interests—dates, parties, and dances engage most of her attention. She still likes sports—swimming or skating, for example—but organized games do not interest her much any longer. She reads, sews, looks in the shop windows, and talks interminably over the telephone. At twenty-one she is even less active, although she develops some degree of spectator interest in active games, but her real diversions are social gatherings, reading, and above all the movies.

The child of either sex who can just barely read likes a small-sized book with many pictures and a story about animals or other children. In the elementary school years, boys like stories that deal with war, boy scouts, athletics, or strenuous adventure. In the preadolescent years many boys develop a craze for reading

an entire series of books, with themes of adventure and athletics. It is not until the later years of adolescence that the romantic novel makes an appeal to boys. Girls show a somewhat different development. During elementary school their interest is chiefly in fairy stories and tales of home or school life. With the beginning of adolescence, they become almost immediately interested in romantic literature. Most girls of thirteen are already reading love stories. They have also a devotion to the continued story in popular magazines and a more pronounced liking than boys for detective stories. Between the ages of 12 or 13 and 15 or 16 boys and girls are markedly unlike in their reading interests because most of the girls are already mature and like adult fiction, whereas the boys still cling to juvenile stories of adventure, athletic prowess, and financial success.

Adolescents thus show their intellectual development by general growth as measured by mental tests, in specific powers or abilities, and by the awakening or changing of interests. In all these lines they show an intellectual quickening and deepening that have always been regarded as an outstanding characteristic of the adolescent years.

Adolescence is, thus, a period of rapid growth in bodily development and of equally rapid change in emotional life, social adjustment, moral attitudes, and intellectual abilities. The boy or girl enters adolescence as a child and emerges, some six or eight years later, as a grown man or woman. Some adolescents pass through the period easily, some have frequent but not serious difficulties, and a few show a sort of emotional and social chaos. The nature of the period depends upon the kind of treatment received from age-mates and adults and upon the kind of adjustments to life already made by the end of childhood.

LUELLA COLE,
Berkeley, California

AESTHETICS, PSYCHOLOGY OF.—To the layman it appears obvious that aesthetic behavior is somehow unique. Studious attention to a textbook on calculus, the butchering of steers, or the tying of shoe strings would not generally be considered as aesthetic. But the reading of a favorite book of poems, the symbolic butchering of men on the stage, or the tying of flowers into garlands would probably

be judged worthy of the name, aesthetic behavior. At first glance the distinction may seem precise and clear. So the discovery that definitions of things aesthetic¹ are quite arbitrary and notoriously subjective of formulation will come, perhaps, as something of a shock to one who has not given the matter considerable thought. Moreover, as the anthropologists continue their work of studying the behaviors of the many peoples of the earth it is becoming increasingly certain that a definition of aesthetic behavior based on studies of a single age or culture is much too limited. We must, then, accept the idea that the aesthetic is a term which covers many divergent behaviors.

Aesthetic behavior is commonly said to be undertaken solely as an end in itself. It is often described as nonutilitarian or as playful behavior and as displaying psychical distance. Tied closely to it are empathic behavior and pleasure. Art is said to be the language of the emotions and always to show the working of some unifying principle. The psychologist, however, is not satisfied with these and the multitude of other criteria of the aesthetic, for he can envisage numerous difficulties in the use of any one of them. Well he knows that all humans, when queried, are prone to cover their real motives with a shell of rationalizations which may be difficult to crack. Artists and art audiences may indeed be motivated in large part by love of the art object itself. But, in addition, they may have cravings for fame, for financial reward, for prestige gained through first-nighting or through being known as art-lovers, for values which are surely not entirely in keeping with the notion that art is an end in itself.

An art object may be intended for use as a dwelling, as an office building, an altar or for some other utilitarian purpose. Now, does this practical, workaday function make it any less artistic? Men differ in the degree of psychical distance with which they view artistic creations. Yet is a man behaving more aesthetically because he views Rubens' "The Descent from the Cross" with more than average detachment? Or is the architect any less artistic because he understands better the structural possibilities of the spindly pillar and so fails to empathize² as does the layman who fears that the ceiling may collapse on his head at any moment?

¹ For this and following references see NOTES, p. 25.

linked to sex. This drive is not expressed in its natural form but rather as a sublimation; it wears a socially acceptable garb. The artist's predilection for the painting of cathedral doors is an expression of sublimated sex, for doors are female sex symbols. And how does Freud know that they possess such symbolic potency? The rules of symbolism, says Freud, have been established through the psychoanalyzing of many thousands of patients.

The answer to the Freudian declaration is that not all his rules have scientific validity. Freud's subjects are unaware of the "meaning" of their thoughts and actions until they are put through a period of indoctrination, i.e., until they are psychoanalyzed. Were they to fall into the hands of a rival analyst their indoctrination would be along different lines and the "meanings" would be different. The notion that Freudian symbols have universal meaning is utter nonsense. There is no proof, then, that all aesthetic motivation is of sexual origin. There are situations,⁷ of course, where the sex motive is obvious. But even here, sex is only one of a number of interacting variables.

The best known tenet of Adlerianism⁸ is the principle which labels the mechanism of overcompensation as the chief source from which motives arise. The overcompensation may be in the area of the defect or in some other field of endeavor. It is the former type of overcompensation which bears particular reference to artistic abilities. Those of us who are endowed with inferior auditory equipment, says Adler, are likely to become musicians; others of us, cursed with color weakness, become for the very reason of this defect, painters. In his writings and speeches Adler has presented corroborative evidence for these claims, but, unfortunately, it is anecdotal in character. Typical of it is the case of Beethoven's deafness. Now this progressive trouble may well have done much to motivate Beethoven musically. But we must remember that Beethoven was musical long before he was deaf. What experimental evidence⁹ the literature yields on defects—and it is scanty indeed—does not bear out Adler's declarations.

We have seen the analysts link aesthetic motivation to sex and to organic weaknesses. Others, while not embracing psychoanalysis, agree with Freud to the extent of assuming that the male sex glands furnish the motivating

forces for artistic endeavor. How else, they ask, can the relative absence of female geniuses be explained? Theorists who argue in this vein ignore the phenomena of social history. To this day the two sexes have not been given equal opportunity or equal pressure to achieve in the world of arts. Until very recently the woman writer was even forced to adopt a male pseudonym to obtain a reading audience. So, it should be obvious that no clearcut answer can be had until the sexes are treated more similarly and are given equally potent reasons for seeking careers.

The advent of the Nazi movement has caused an intensification of the belief that each race has unique motivational resources which make its members peculiarly successful in certain types of activity. The proponents of this view have not bothered to indicate the sources of these motivational differences except to assume that they are somehow linked to biological structures. Neither have they worried over their numerous and contradictory uses of the term "race."

Racists who consider themselves "Nordics" have staked claims for their superiority in most creative lines. But because aesthetic achievement of a non-literary sort has probably never been regarded by them as highly as has great accomplishment along literary lines they are often willing to grant to the "Alpine," the "Mediterranean" and even to the Semitic peoples preeminence in the other arts. Of course they fail to note that careers in music and painting are often among the few open to "inferior" groups.

With the advent of tests of artistic talent there arose the hope that racial differences could be analyzed in a truly scientific manner. Unfortunately, this hope has not been realized. Mental tests, whether they measure IQ's, or "talent" in one of the several arts, cannot transcend the particular cultures in which they have been standardized. Within a culture, test differences among the "racial" subgroups are slight at best. Intragroup differences are far more striking than the intergroup. Hence, to state a person's "race" is to say nothing important about his artistic potentialities.

It has been held by some writers that the genius is a psychopathic sort of person who derives his motivations from his maladjustments. Adjust him perfectly, and, presto, he will lose

all drive toward creativity. It goes without saying that this blissful state of perfect adjustment has never been adequately defined, much less reached. So we must limit our discussion to the more obvious degrees of maladjustment.

The few data so far assembled would seem to show that the artistic are no oftener psychotic than are their less artistic fellows. However, common observation might lead us to suspect that the artistic are more commonly psychoneurotic. Such may indeed be the case. Yet granting the possibility, we would still need to know whether the psychoneurosis tends to precede or follow the artistic drive. The phenomenon of "artistic licence" and the beliefs of many onlookers that "all artists are somewhat crazy" may in themselves have considerable potency in forcing oddity in behavior. At any rate the issue is too unclear to warrant further comment.

Strange but much believed are a number of statements concerning relationships between aesthetic abilities and physical characters. It is said that pointed or angular ears are "un-musical" as sound is curvilinear. Players of certain wind instruments allegedly possess extremely even front teeth. While almost all trombonists are bald, pianists tend to be blessed with a wealth of hair. The fingers of violinists (as well as thieves and surgeons) are longer and narrower than those of the average man. Such statements can be matched for the other arts. Yet even if they were to be substantiated, which the majority have not been, they would yield data of little worth on the motivational issue. We should still wish to know how the possession of long fingers forces one to take up the fiddle, or the blessing of regular teeth a wind instrument.

So far we have discussed alleged secondary motivational factors which probably no one would consider to be the most basic. Usually there is made the added assumption that he who achieves in the arts has been blessed with a particular genetic structure. It has even been assumed that the several artistic capacities are inherited as dominant factors. For proof of these genetic theories recourse is usually had to the analysis of family lines. The Bach family has been followed from generation to generation with only the ambiguous finding that for a time the number of musicians from generation to generation increased and then decreased.

But was the ultimate total eclipse of this great Bach family due to unfortunate marriages, to the changing socio-economic conditions of Germany or to a combination of these factors? It would seem obvious that the reasons for the fluctuation in the number of the artistically brilliant can never be learned by the techniques of genealogical research.

The difficulty with genealogical research rests in part on the faulty conception of heredity accepted by these family analysts. Happily, at the present time there appears to be a growing tendency to regard nature and nurture not as two mutually exclusive forces but rather as interweaving variables, each meaningless without the other. We see before us artists who seem to have emerged from most unpromising environments. We note that others with perhaps equally "good genes" may find such "bad" surroundings a complete block to all creativity. But we cannot be certain that such observations are sound until we get better tools for studying the stimulating character of our myriads of environments.

We have seen that little or nothing is known about man's artistic inheritance. We have reviewed certain of the alleged secondary sources of motivation and have found a rather similar state of ignorance. And now it must be admitted that little more is known of man's cultural motivations. Yet common observation tells us that they are powerful and that they affect men's responses to the last detail. Parental proddings, praise received at school, the desire to follow in the footsteps of some beloved model, or the opportunity to excel his fellows, may furnish just the stimulation necessary to start a youth into a career in the arts. Social proddings can, superficially at least, be analyzed further. A mother may force her son to take lessons on the violin because she has longed for lessons herself. A father may desire his daughter to be socially attractive and feel that the possession of art skills will aid in furthering this aim. Many of us have listened to our first chamber music because "it was the thing to do." Later on, after much suffering, we have found delight in the music itself.

The analyses of environmental motivations can be pushed further and further back. Why has the mother longed to take music lessons? Perhaps she has seen in the lesson a chance to push herself ahead socially, to break the routine

of housework, or to make herself feel that she is doing something worth while. But why does she wish to succeed socially, to avoid routine, or to do something worth while? To answer these questions the analyses must go ever deeper into the structure of the mores. Presumably every motivation is socially determined by thousands of interacting variables. To give any more than a superficial social history of any motive would necessitate a stupendous amount of probing into the history of the individual. Even then, all of the necessary information could probably never be obtained.

Life is filled with conflicts. We push on in one field and succumb to the adverse pressures of other fields. The artist is one who has developed a proficiency in color, line, tone or in some other art medium. His audience may listen to or view his works without sensing the motives behind their creation. Each artist's motivations may be quite different from those of his brother. And to learn why a particular person is motivated to view a painting or to listen to a piece of music demands the same type of detailed analysis of the individual's personal and social background found necessary in analyzing the motivations of the creator of the art work. The answers to the question of artistic motivation, thus, must be sought in the workings of social and clinical psychology.

ART STANDARDS

The belief that certain art objects are inherently good and that others are naturally bad is apt to strike the layman as sound common sense. The view which opposes this absolutist notion, the relativistic, considers beauty to be a function of the relationship between art object and percipient, with the relationship varying from time to time and from place to place. It is claimed by the relativists that the changes in art tastes, recorded by the historians, could not have occurred if standards were absolute. They point also to the undeniable fact that the absolutists are invariably ambiguous in their descriptions of art principles. Indeed, their absolutes have become a veritable Holy Grail, ever sought but never found. The absolutists concede that history discloses apparent changes in standards, but maintain that men are still groping after the absolutes, and, in so doing, discard from time to time their false standards. The absolutists' criteria of "goodness" are not

always limited to the qualities of the art object but may also include the motives of the creator of the art object.

Quite typical of the attempts to assemble criteria is that of Howes¹⁰ who has offered as distinguishing marks of "bad" art: lack of sincerity, shallowness, self-deception of the real nature of the emotion, sentimentality, unconscious abandonment of restraint, and the use of the cliché. This list, it must be admitted, looks impressive. But bold, indeed, is he who would offer to separate any one of these criteria from its subjective covering and put it into scientific terms. If a man cannot always be certain of his own motives how well can he judge the sincerity or the self-deception of an artist, particularly if the latter has been long dead or is from another culture? Almost identical condemnations hold for shallowness and for the other criteria except the cliché. And, after all, why should we worry over the mental workings of the creator of the art object if it is the creation to which we are supposedly reacting?

The cliché, by its very definition, is an experiential affair. No artistic fragment can become hackneyed except through use. An element of art is ever fresh to the uninitiated while at the same time, perhaps, it is a cliché to the sophisticate. A musical phrase may seem novel at one period, a cliché at another, and again novel at a still later period. Thus, if an art element can be both good and bad at the same time the criterion of the cliché can hardly serve the purpose of the absolutists.

At first glance C. E. Seashore's definition of beauty as "artistic deviation from the rigid"¹¹ might seem to supply an objective criterion. The painter never paints with photographic accuracy. The vocalist and the violinist have their vibrato. And much the same situation occurs in the other arts. Mechanically perfect creations and renditions are frowned upon. A consideration of the issue, however, will show that the term "artistic" expresses an unknown quantity. The analyses of musical performances that Seashore and his colleagues have made, splendid and important as they are, can do no more than point out current practices, and, to a lesser extent, what were the practices as far back as phonographic recordings are available. They cannot disclose absolutes.

Kate Gordon¹² and a number of other ex-

perimenters have done worth-while analyses of pooled judgments (see page 24). When two or more large groups of subjects with comparable cultural backgrounds are asked to rate the "goodness" of art objects with which they are reasonably familiar the group judgments will agree extremely well. Picked at random, person A may disagree violently with individual B. Yet the composite or pooled rank values voted by any one group of subjects will correlate very well with rank values given by the other groups. It should not be thought that the pooling technique discloses absolutes. Although certain theorists (but not Gordon) have assumed that such is the case it should be obvious that in almost any art field pools taken a century apart may agree only in slight degree. Pooling procedures simply bring out the contemporary cultural commonalities.

What has been taken by some as an attempt to describe absolutes can be seen in Birkhoff's¹³ *aesthetic measure, M*, which is regarded as a function of *O* (order or unity) and *C* (complexity or variety). In finding *M*, short work is made of *C* which is rather simply and arbitrarily defined. *O*, however, is split into a number of subfactors whose weights are frequently very difficult to figure with the aid of the Birkhoff rules. As Birkhoff admits that *O* and *C* represent social values he himself is not an absolutist.

A number of experimenters¹⁴ have attempted to check Birkhoff's values against others obtained directly from group preferences. Just what the moderate correlations which are usually found indicate is not entirely clear. But since Birkhoff must have followed the professional theorists rather closely in formulating his rules it can be guessed that the rather mediocre relationships so far obtained indicate merely the expected lag between present preferences and the views of the (usually) long deceased art and music theorists who have formulated our traditional rules.

From time to time since early days the idea has been expressed that a geometrical analysis of any visual art sample will disclose the reasons for its lasting beauty. It is sometimes assumed that the viewer perceives, consciously or unconsciously, the geometrical relationships involved, e.g., the squares and root rectangles found in the dimensions of the Parthenon. Many art objects are admittedly symmetrical in a static

sense. Others are said to possess a more dynamic type of symmetry. R. M. Ogden¹⁵ has seen in this naïve geometry of symmetry a mechanism by which he could link the gestalt doctrine of organized or symmetrical wholes to the beauty of art. He says: "While strict adherence to either static or dynamic symmetry is not called for, one or the other of these principles must be followed; otherwise, the parts will not find their due places within the whole, and the appearance of the whole will not be that of a harmonious arrangement of parts" (p. 201).

G. T. Fechner,¹⁶ often termed the founder of experimental aesthetics, can with considerable accuracy be termed an absolutist. By laborious tests Fechner reached the conclusion that one unique arrangement of parts was, aesthetically speaking, the best. This he termed the golden section.¹⁷ Fechner saw the golden section as the preferred shape for rectangles and as the most pleasing division point of a line, e.g., where the arms of the cross cut the staff. But whether or not the principles of symmetry and the golden section are innately perceived as "proper" it should be noted that present-day preferences are not always what the absolutists might anticipate. This is especially true of the golden section which, while reasonably well liked, often falls well below first place in a preference series.

One attack on the universality of art standards might conceivably be launched through a study of the "lasting quality" of artists and art objects. Any such genetic study¹⁸ will show that many men, like J. S. Bach, were practically neglected in their own time but achieved fame at some later date. Others, once famous, had in store for them a toboggan-like slide in popularity. Rossini comes to mind in this connection. Still others, like Beethoven, early achieved an acclaim which has lasted to our day. Experimenters¹⁹ have tried to telescope history by repeating over and over again a few musical compositions ad nauseam. The effects were as anticipated. Extremely simple compositions and those composed largely of clichés wore down the listeners faster than did those whose structures showed more complexity and novelty. But, repeated many, many times a day, even the latter compositions wore out their welcome. Here, then, is a point worth noting. Artists whose productions offer us too little in the way of complexity and novelty are not so likely

to remain as eminent as are their somewhat more original colleagues.

In this section we have oversimplified the position most theorists take on the question of absolutes. Few nowadays hold to one hundred per cent absolutes and no theorist can help making some value judgments. A sensible mid-position is that offered by Chandler²⁰ who holds that "the consensus of apparently cultivated persons throughout many generations will approximately represent humanity at its best and therefore be approximately objective" (p. 635). The Chandler view would cover the idea that a given art object can be the "best" of its particular school. For just as soup is desired early in the meal but not at dessert time and can be voted by soup lovers as good or bad, so hot jazz and Bach's counterpoint serve us differently as they follow or break the socially agreed-upon rules of their respective schools; yet specimens of each can be rated as good or bad. Bach's Concerto in D Minor is, in an absolute sense, no better nor worse than jazz. It is not a rival of jazz but it is on a different continuum altogether. The effect of a Bach composition on our musical lives is so much more lasting we term it "serious" music and pay it far more attention in our histories of music than we do jazz. But Bach would serve but poorly wherever jazz now reigns supreme.

TESTS IN AESTHETICS

The tests employed in the arts can be roughly divided into taste, "capacity," interest and attitude, and achievement, with some few classified into more than one of these categories. While the vast majority have reliabilities which are adequate for group work their validities have often been questioned.

Typical of the taste tests in the music field is the Hevner-Landsbury.²¹ Musical phrases in pairs are presented to the subject who must decide which pair member is "more pleasing, more appropriate, more musical." The Meier,²² a good sample of the taste tests in the field of painting, is constructed on a somewhat similar plan. The field of literature also has a number of taste tests built along this general line.

The "capacity" tests may be comparative or analytic in type. The drawing scales²³ are representative of the former; many drawings, after having been evaluated by experts, are arranged in the form of a scale and are given values.

The handiwork of the person to be tested is compared with the specimens of the scale and is assigned the scale value of the specimen it most resembles.

Behind the construction of the analytic tests is the much-disputed philosophy which holds that an art area can be broken down into fragments each to be tested without much relation to the others. The best-known tests to emerge out of this philosophy are the Seashore Measures of Musical Talents²⁴ which test in the fields of pitch, time, loudness, rhythm and timbre differences as well as tonal memory. The Seashore measures have proved of greatest value in the sifting of those people who will benefit least from training in music. The Seashore battery has several rivals, some of which test in the same areas while others measure such matters as tonal sequence, absolute pitch, interval recognition, etc.

The Study of Values²⁵ is a test which differentiates between six interest types of which one is the aesthetic. As might be anticipated, artists and musicians tend to make their highest scores in this interest type. Best known, perhaps, of the interest measures is the Strong Vocational Interest Test²⁶ which yields occupational scores which can be compared with those made by musicians, artists, architects, and author-journalists. What the Strong test does, in effect, is to compare the subject's interests with those of some two hundred or more members of each of these artistic professions. Assuming proper ability and training, the tester attempts to appraise the community of interest between the man tested and the members of these several occupations. Another approach to the testing of interests and attitudes is through the rating and formal attitude scales. The best-known aesthetic test in this category is the Hevner-Seashore²⁷ which measures attitude toward music with a formal-attitude scale built somewhat along lines of the now popular Thurstone-style test.

The numerous achievement tests now on the market resemble in all essential details the tests of accomplishment found in the other disciplines. Typical is the Kwalwasser-Ruch Test of Musical Accomplishment²⁸ for use in grades 4 through 12. This test has sections devoted to knowledge of musical symbols and terms, time and key signatures, note and rest values; to recognition of syllable and pitch names, and

familiar melodies from notation; and to detection of pitch and time errors in familiar melodies. There are also available standardized tests in which the subject is rated on the quality of his artistic performance.²⁰

It is clear that the aesthetic tests are, in the main, measuring variables which do not overlap greatly with academic intelligence. So, it is often the practice to add an intelligence test to a battery of art or music tests to facilitate the work of forecasting. Naturally, this would not be done were it not for the evidence that better than average intelligence is needed for success in aesthetic endeavor. Meier,³⁰ who has done fundamental work in the psychology of art, makes intelligence one of his six essential factors to creativity, the others being: energy output and perseverance, manual skill, perceptual facility, creative imagination, and aesthetic judgment. (The last-mentioned factor is measured by the Meier test mentioned above.) Of course anecdotes can be heard which tell of idiot savants who have done work of excellent grade in some one of the arts. But when these stories have been checked it is usually found that the so-called idiot savants either have no real ability or are psychopathic rather than feeble-minded.

LINKAGES IN THE ARTS

The stereotype of the artist is sometimes said to be that of a man with abilities so narrow that he can achieve in only one field of endeavor. The true picture, however, seems quite different with versatility rather than narrow channeling of interests and abilities the rule. The literature provides striking examples of men eminent in several art fields and of geniuses who obviously possessed the potentialities for great achievement in many lines of endeavor. But while many of the arts call for somewhat similar interests and abilities, music does not demand interests at all like those of its sister arts, if we can take the Strong interest patterns at face value.³¹ The interest profile of the musician is so different from that obtained from men in any of the other artistic occupations that it is usually not placed in the art category when professional groupings are made. Common observation seems to substantiate this finding.

A number of artists who hold that the arts are all basically one point to the phenomenon of chromesthesia or color-linkage to prove their

contentions. As one stage artist remarked to the author: "I never worry about the rules of color harmony. As I know what colors and tones are linked I merely translate the consonances of music into color and thus have answers which just can't be wrong." This craftsman was only temporarily dismayed to learn that his particular color-tone linkages were not shared by all other chromesthetic individuals. Like many others in similar situations he assumed that his alone were the "proper" linkages. Unfortunately for science, he and his fellows can rarely recall just when these conditionings—if they are conditionings—were formed. The dearth of information as to the origins of chromesthesia and the fact that the creation of extreme chromesthesia in the laboratory has so far proved impossible have led certain theorists to set up neural irradiation and other biological notions as rivals to the association hypothesis. A majority of the population have slight color-tone or tone-form associations.³² Ordinarily, however, the terms chromesthesia and synesthesia are reserved for the relatively small number of cases in which the images are of almost hallucinatory intensity. But neither the existence of an occasional chromesthetic nor that of the more common "visual-auditory associator" proves that there is an innate linkage between the auditory and visual arts.

TYPICAL EXPERIMENTAL DATA FROM THE MUSICAL ARTS

Vibrato. Contrary to popular belief, professional musicians only rarely render steady vocal tones. In about 95 per cent of the tones the pitch wavers up and down in a regular fashion. The range of each oscillation is from three-tenths of a tone to a little over a tone with the average at half a tone. The number of pulsations a second is approximately six. The string vibrato tends to be one pulsation a second greater, on the average, but spreads over only about a quarter tone. There are also intensity and timbre pulsations in both voice and strings and some vibrato in tones given off by other sorts of musical instruments. The vibrato³³ is usually considered to be the most useful of all musical ornaments.

Rhythms. Because of the relative absence of five- and seven-point rhythms in occidental music it has been popular to suppose that nature had endowed man with the capacity to

handle only two- and three-point rhythms and others based on these less complicated types. This view, however, is anthropologically naïve, as there can be found in the Orient many examples of five- and seven-point rhythms. Moreover, Max Meyer²⁴ has shown that occidentals too can achieve proficiency in what to them are the rarer rhythms. Meyer trained subjects in a laboratory to tap these rhythms by striking a baton against a series of buttons arranged in a wooden frame. With a training period of five minutes a day for four weeks his subjects reached a level of facility about equal to what they had previously had for two- and three-point rhythms. These and other experiments on cross rhythms indicate that the occidental musician has many rhythmic resources he has not so far exploited.

Damper-Pedalling. The reproducing piano such as the Duo-Art furnishes the researcher in aesthetics with a type of apparatus by which he can study the piano performances of the leading virtuosos. The player-piano is particularly useful when the idiosyncrasies of different performers playing the same composition are to be scrutinized. One of the pioneers in piano-roll analysis, C. P. Heinlein,²⁵ has found that there is surprisingly little agreement among leading pianists on the proper uses of damper-pedal patterns. This lack of agreement is reflected in the fact that a number of different patterns are generally acceptable in the performance of any given musical composition. It is well that this is true, for no professional pianist whom Heinlein studied was able to duplicate the pedal performance he himself had made ten minutes earlier. In fact, so little formal attention is currently paid to foot action by teachers of the piano that even the musically trained are apt to conceive damper-pedal differences primarily as differences in finger action on the keys. Schooled in the notion that all dynamics come from key action, they do not visualize the real role of the feet in piano performance.

Baton Movements. In our discussion of the vibrato we called attention to the fact that many teachers consider the "good" tone to be steady while in reality it is a "wobble." A study by Bartholomew²⁶ has shown a somewhat similar misconception in respect to baton movements. The textbook diagrams show a preponderance of straight-line motions and periods of relative rest at the beat-instants. To verify these rules

Bartholomew attached a tiny lamp to the end of a baton so wired that the light dimmed at the exact instant of the beat. The path of light was then photographed by a time exposure in a dark room. In his analysis of the baton movements of conductors Bartholomew found curvilinear rather than straight-line motions and points of rest closer to the "ands" after the respective beats. The fastest speeds were often at the beat-instants. In 4/4 time the second, third and fourth beats tended to occur at troughs before the sides or top of the arm sweep was reached. Here, then, is an illustration of lack of realism in music education.

Industrial Music. More and more music is coming to be a part of the environment of the manual worker in the factory. Although it is difficult to prove that music directly raises production, it does appear to lift morale, if properly handled, and so, without a doubt, has valuable indirect effects. But not all types of music are liked equally well by the doer of repetitive work. Popular music of the hit-parade sort seems to be the most preferred with patriotic, Hawaiian and waltzes also well liked. "Semi-classical" comes well down the list of preferences, "classical" falls even lower and the blues come last in preference. There is now a special attitude scale available for the measurement of the musical preferences of industrial workers.²⁷

Improvability of Pitch Discrimination. Only a relatively few years ago children who could not carry tunes were common in the early grades. These monotones, as they were called, were usually boys and were assumed to be suffering from structural defects. But since that time a reevaluation of the arts in the school curriculum has led to better motivational devices. Hence, the boys of today more generally learn the concept of pitch, and monotones have become almost totally extinct.

While willing now to grant educability to monotones many testers are still loath to believe that adults with "reasonably poor ears for pitch" may be given better abilities through training. Nevertheless the task of proving that improvements are possible has been attempted by Wyatt²⁸ whose 16 subjects tested "low average" on the revised Seashore "Pitch Discrimination B" test (see page 18) and "poorly" on a specially devised pitch test. Wyatt gave her subjects 16 hours of training (one hour a week) in the discrimination of oscillator tones (500

movements of the eye during word reading can be studied. These devices have been adapted by Jacobsen,⁴⁴ Weaver⁴⁵ and others for use in the study of the reading of music, a type of reading in which vertical as well as horizontal movements must be measured. In the Weaver experiments photographic records of the eye movements were synchronized to records of performance on the piano keyboard to make possible determinations of eye-hand span. Conservatory students were given three selections of eight measures each to read—one, a hymn; another, a two-part Bach minuet; and the third, a single melody with supporting chords.

Among the many findings the following are of particular interest. The average number of notes played per reading pause was between one and two; the pauses lasted between .27 and .53 sec.,—longer than for word reading. Chords were not always read at one glance. Rather, the treble parts tended to be read before the corresponding bass portions. It was found that the eye-hand span was quite variable with never more than eight successive notes or chords between eye and hand. Although there tended to be two styles of reading—"a regular alternation of almost vertical movements of the eyes from one half of the staff to the other half and frequent horizontal movements on one half of the staff with relatively few movements between the two halves of the staff" (p. 28)—there seemed to be no basis for distinguishing types of readers. Weaver favors the "horizontal" form of reading.

TYPICAL EXPERIMENTAL DATA FROM THE OTHER ARTS

Ocular Behavior and Pictorial Balance. At the turn of the century Stratton⁴⁶ demonstrated that in the viewing of a serpentine line the eyes do not follow the curve smoothly, as introspection would suggest, but move, rather in an irregular pattern. Feeling that the art experts might be equally in error when they consider pictorial balance a matter of eye pauses, Langford⁴⁷ studied the patterns of eye movements made by college students who were viewing pictures previously judged for goodness of balance. The Weaver adaptation of the Dodge method of eye-movement photography was employed (see above). Analyses of the data revealed large differences in the eye-movement patterns of different individuals looking at the

same picture. No relationship was found to exist "between the judgment of the balance of a picture and the duration, position, or pattern of ocular fixations on either side of the central vertical axis during free observation of the picture" (p. 322). Once again, then, we have a situation in which the beliefs of the artist do not check with the facts of science.

Colors for the Stage. Earlier in this section we commented on the fact that an artist's chromesthetic responses cannot serve as a valid guide to his use of color on the stage. This is not to say, however, that there are no commonly held associations between color reaction on the one hand and temperature, kinesthetic and organic discrimination on the other. Indeed, there are many generally shared associations, a fact shown in a series of studies by Ross.⁴⁸

Carefully calibrated Brigham gelatines were placed in front of a projector whose normal illumination on an area 160 by 130 cm. was 6.5 foot-candles. Each color was shown for 90 seconds during which time the subject filled out rating scales having to do with such issues as emotionality, affectivity, activity, tension, temperature, tragedy, comedy, melodrama and romance, and check lists which contained descriptive adjectives of the sort Hevner (see page 18) has employed with her work on the expressiveness of music. Ross found that "colors which are rated as emotional tend also to be tense, melodramatic, and possibly tragic and romantic. Colors which are rated as active are associated with comedy; hot temperatures are ill-suited for tragedy. Colors which are rated as tense are associated with emotionality, tragedy and melodrama. The warm colors are comic, the cool ones tragic, and colors suited for tragedy are also suited for melodrama" (p. 183). When the colors were arranged in order from hot to cool the following sequence appeared: red, orange and purple, orange-yellow and purple-violet, yellow and violet, blue and yellow-green, blue-blue-green and green, blue-green.

Universality. The great philosopher Immanuel Kant held that sense pleasure could be distinguished from aesthetic pleasure through two characteristics that the latter alone possessed—disinterestedness and universality. With the first of these criteria we need not be concerned here. And the second can apparently be

rejected on the basis of sound experimental evidence.

Gordon,⁴⁰ a student of aesthetic problems (see page 25), chose ten pictures of women's faces, some extremely beautiful and others rather ugly, and showed them to two groups of 100 persons each. The beauty ranks given by the members of each group were separately pooled. The rank orders of the two pools were found to yield a correlational value of .99 even though there were many disagreements among the members of each group. In a second experiment ten rectangles, each containing 100 sq. cms., were judged for preference (see page 25) by two groups of similar size. Although disagreements were again numerous within the groups, the two pool orders gave a coefficient of correlation of .98.

In her third experiment sense pleasure rather than the pleasantness of beauty was studied. Boides giving the odors of lemon, cinnamon, peppermint, bergamot, lavender, eucalyptus, tansy, creosote, valerian and asafoetida were given to two groups of 100 each for ranking from most pleasant to most foul. This time the degree of agreement within each group was far greater than in either of the other groups whose members were supposedly making aesthetic judgments. Here, then, is proof that ratings based on sense pleasure can be at least as uniform as those based on beauty. In fact in this study the ratings for sense pleasure are more uniform. Kant's criterion, it would seem, was ill chosen.

An Attitudinal Profile Estimated. As the mental test is a phenomenon solely of the twentieth century we must employ other, more indirect, procedures if we desire to assess the attitudes of the aesthetically great of the previous centuries. One of these indirect attacks on attitude can be seen in a study by Ferguson⁵⁰ who combed through the biographies and the works of Jonathan Swift in an attempt to learn how Swift would have answered the questions in *A Study of Values* (see page 26) had it been available in his day. Measures of the completeness of the data were figured by taking the square root of the per cent of the questions for which answers could be found. These values ranged from .77 to .87 for the various sections of the test. Changing Ferguson's raw data into percentiles we find Swift's profile to be approximately as follows: 28 per-

centile in theoretical interest, 50 in economic, 42 in aesthetic, 53 in social, 55 in political and 72 in religious interest.

Craftsman Ancestry. N. Meier,⁵¹ who has spent many years studying the development of drawing ability in the child, has decided that craftsman ability is an essential part of art talent (see page 25). If, then, craftsman ability is so extremely important we may well ask whether relatively more craftsmen can be counted in the talented child's family line than among the ancestors of the less talented.

In an attempt to throw light on this problem Meier has contrasted the ancestries of 176 unselected high-school and college students with the family lines of 644 art students and artists. He found that over three times as many of the unselected as of the artistic group knew of no craftsmen among their ancestors. And, on the positive side, Meier found the average number of known craftsmen to be over twice as great among the ancestors of the artistic as among those of the unselected. Whether we agree with Meier that there is a general constitutional stock inheritance of craftsman capacity or believe that this ability comes into the picture solely or in large part by way of cultural inheritance, we must admit that it tends to run in families and so could conceivably function either biologically or culturally.

Behavior of the Museum Visitor. Starting in 1928 there has been a succession of interesting studies of the behavior of visitors to museums and art galleries. Such research can be very practical, for what is learned about the ways of the visitors can often be used to make the exhibits more effective.

In the most recently published study of the museum visitor Yoshioka⁵² and his associates traced the paths of 3005 visitors through the Medicine and Public Health Building at the New York World's Fair in 1939. It was found that the three types of routes most frequently traversed were the "direct"—from an entrance to an exit other than itself—the "circuit"—from an entrance back to itself as an exit—and the "reversible"—direct route with a divergence. Yoshioka feels that these behaviors can be described in terms of certain principles of animal psychology. He regards the "direct" type as resulting chiefly from direction-orientation, the "circuit" type from exploratory tendency and the "reversible" from an interplay of the two.

He concludes that exhibits can be made more attractive at key positions in the museum so that the tendency to leave at the nearest exit will be lessened. Or, in the phrases of animal psychology, the exploratory tendency can be made more dominant over direction-orientation.

Apparent Distance of Colors. The influence of hue and brightness on estimations of weight, size and distance have been studied in several sets of investigations. The most recent of these studies, one by Taylor and Sumner,⁵³ is on the apparent distance of a set of differently colored tubes which had previously been measured for physical brightness, i.e., for percentage of reflected light. The tubes were fitted over two tiny poles in a lightproof box and were illuminated by a 40-watt lamp. One pole was always covered by a gray tube and was stationary. The other, covered in turn by each of the remaining tubes, could be pulled either forward from the back of the box or backward from the front until it seemed to be as far from the observer as was the gray-covered pole.

Each of the experiment's eleven subjects pulled the movable pole forward 50 times and backward 50 times. When these judgments were averaged it was found that a coefficient of correlation of .99 existed between the relative brightnesses of the colors on the movable pole and their average distances from the stationary pole. Thus, the yellow with a brightness of 76 per cent was a distance of 7.05 mm.; the white with a brightness of 75 per cent, 6.71 mm.; the green with a brightness of 32 per cent, 1.74 mm.; the red with a brightness of 12.5, 1.36 mm.; the blue with a brightness of 7 per cent, .27 mm.; and the black with a brightness of 2.3 per cent, .33 mm. In other words, the brighter the color the closer it seemed to be to the observer.

Suggestion in Art Judgment. The social psychologists have repeatedly shown that verbal suggestions can markedly affect aesthetic judgments in both the musical and graphic-art areas. Sisson⁵⁴ has verified these earlier findings and has added to our body of knowledge the fact that nonverbal cues can also modify aesthetic response.

Ninety plates from the first edition of Meier's Art Judgment Test (see page 19) were separated into three equal sets and were presented to 25 subjects under three different experimental settings. The first thirty were offered

for judgment along with verbal suggestions such as "The left-hand picture is very famous. The right-hand one is a more modern interpretation." The subjects were told to disagree with the experimenter if they saw fit. Only half of the plates the experimenter indicated as "correct" were so designated in Meier's scoring key. Each plate offered as "correct" by the investigator had an obvious but unexplained check mark in the lower margin. The second set of plates also carried the unexplained check marks but no comments. The third set had the usual Meier directions with neither check marks nor comments.

The plates Meier's stencil terms "correct" were preferred by 15.27 subjects who had neither been given the comments nor had seen the check marks, by 16.86 stimulated only by the check marks, and by 19.19 who both had heard the comments and had "seen" the check marks. The plates Meier had classified as "incorrect" were preferred by 6.86 subjects when no suggestions were given, by 7.81 when the cue marks were present, and by 10.64 when both the checks and the verbal suggestions were given. The differences as found were small but consistent and in line with common sense.

Sensory Memories and the Ability to Draw. It has been customary for the teacher of drawing to think of his task as primarily the teaching of graphic expression, a job which is without doubt of extreme importance. But Lark-Horovitz⁵⁵ has clearly shown in a series of observations that even more important is the strengthening and development of visual memory. She feels that the verbal aspects of training have been overemphasized with the result that the adult who has gone through the traditional school-training still keeps his confused imagery and draws in a childlike manner.

In one of the Lark-Horovitz experiments 170 adults were asked to draw ten common objects of the order chair, duck, violin, etc. Race, profession and general background appeared to have no connection with the ability to draw well. The uniformly poor showing of these adults appeared to be due mainly to defects of memory. These the investigator divided into three categories. Many subjects appeared to have *blurred mental images* even when unaware of this state of affairs. A common trouble could be traced to the possession of *clear but fragmentary visual images*. There was also a

considerable lack of real knowledge of the object. Lark-Horovitz concludes that the mental images of her subjects were "sense-mixed," that they were composed of a medley of visual, tactile, auditory and olfactory memories. Her questioning showed that when these adults attempted to reconstruct the object logically they found their mnemonic pictures unfit for graphic expression.

The Arousal of Ideas in "Good" Art. The belief that "good" art is, on the whole, more conducive to imaginative response than is "bad" art seems to be substantiated in a recent study by Patrick.⁵⁰ Six professionally-drawn landscapes and six by amateurs were presented to 20 subjects who were told to talk aloud as soon as the drawings were given them and to say anything that came to mind, no matter how irrelevant. In half of the observations the time for speech was unlimited and for half it was limited to 10 minutes per picture. All changes in thought were recorded—some 240 in all.

Under each condition there were substantially more thought changes while viewing the professionally-drawn pictures, and, during the untimed observations, the subjects spent relatively more time on them. Self-projection also appeared more often while the "good" pictures were being viewed. Patrick concludes that "good art stimulates greater mental activity and imagination than poor art does."

PAUL R. FARNSWORTH,
Stanford University

NOTES

¹ In this book the words "aesthetic" and "artistic" are used interchangeably. While certain aestheticians differentiate between the terms it seems unnecessary for the psychologist to do so.

² The importance of empathy in aesthetics is defended in the interesting book by H. S. Langfeld, *The Aesthetic Attitude*, 1920.

ALCOHOLISM.—Alcoholism is difficult to define since it involves an intricate and qualitative measurement. Not only does the tolerance of individuals for alcohol vary, but an individual's reaction in itself is variable and unpredictable. The only possible evaluation is based on the behavior of the person. A social drinker is able to control his desire for alcohol so that its use is restricted to socially acceptable situations, although at "appropriate" occasions intoxication may result. The alcoholic is handled by alcohol, his drinking is not a part of a social situation but a substitution for it, and alcohol has become for him a *habit forming drug*.

The alcoholic today is a serious social and medical problem. Although the influence of alcoholism on crime and the family has doubtless been exaggerated, alcoholics form a large percentage of our mental hospital admissions, and a recent survey reveals 600,000 chronic alcoholics and 2,000,000 heavy drinkers and potential alcoholics.

Pharmacological research at the Yale Laboratory of Applied Physiology has definitely demonstrated that alcohol is a depressant and not a stimulant. The feeling of well being that an alcoholic experiences on first drinking comes from a narcotization of the higher centers of the nervous system that results in temporarily decreased worry, irritability, and anxiety much as novocaine quiets an aching tooth. With worry stilled and anxiety eliminated, the drinker feels exhilarated and "stimulated," although the effect on the brain and nervous system is just the opposite. This holds true for both the social drinker and the alcoholic. It is this feature which makes the mixing of alcohol and driving so dangerous.

Alcoholism—in a special sense—can be considered a symptom and not a disease. In groups

it is a symptom of widespread social pathology and in individuals it is a symptom of mental and emotional pathology. As soon as its symptomatic nature is generally recognized, its cure will become possible, for most of our present methods are simply an alleviation of the symptom rather than a direct attack on the underlying pathology; as a result such methods are notoriously ineffective. It is as foolish to prohibit alcohol because some people drink to excess as to abolish money because some steal or hoard it. A direct assault is indicated on the conditions that drive man to drink.

If, as we have learned, alcohol narcotizes physical and psychical pain and relieves—albeit temporarily—feelings of anxiety, inferiority, etc., it becomes obvious that it is necessary to eliminate the causes of these feelings. These can be most conveniently divided into two groups: (1) The effect of the prevailing culture and economy, and (2) The individual's inner adjustment to reality.

Our culture today is a traumatizing one. Insecurity and inequality are rampant and the opportunities for success are contracting at a time when ambition is over-stimulated by an inept school system and asocial advertising. Economic and social democracy has lagged behind political democracy, resulting in slums, unemployment, labor strife, and family disorganization. War has added its bit to the mounting toll of frustration, bitterness, and failure. In a culture where success is measured by a money standard, the vast majority are doomed to failure or mediocrity, no matter what their talents or accomplishments. A mounting panacea for these economic and social anomalies has been, for some, a steadily increasing resort to alcohol to lose for a few hours the sense of personal failure, frustration of desire, or feelings of inferiority and thwarting.

It must be noted, however, that most individuals do not become alcoholics due to the fact that their personalities are sufficiently well balanced and maturity has been achieved. In immature, unstable personalities these conflicting economic and social forces which the person is at odds with but has no real means of changing, produce individuals peculiarly susceptible to alcoholism. Contrary to most lay opinion, it is not lack of will or moral turpitude, but powerful, psychic drives and urges that are responsible.

Apart from the contributory social factors, there are strong psychiatric ones. These can be best grouped under the designation of psychic pain. The ramifications of this are widespread and include unsatisfactory sex life, feelings of inferiority, marital and business troubles, organ inferiority, homosexual drives, masochistic or sadistic tendencies, and as a release from the tensions of everyday life which the inadequately balanced personality cannot face. There are, of course, psychotics, neurotics, and psychopaths who are alcoholics. In such cases, the symptom is a manifestation of basic psychiatric malfunctioning and treatment and cure are coincidental to the therapy of the basic personality or physical malfunctioning. There are also a few who drink to narcotize incurable physical pain.

For overwhelming practical reasons, the therapy of the alcoholic must begin first with the individual. A good beginning will have been made when the medical profession, the alcoholic, and the general public are made aware that the alcoholic is a sick person. This is not to imply that all alcoholics are curable: there are many who have so few wholesome qualities left to build on that therapy is hopeless. Some alcoholics, however, are curable and many alcoholics in their primary stages are amenable to therapy. One of our greatest tasks in mental hygiene, then, is the early discovery and diagnosis of alcoholism, and its prompt treatment.

The prophylaxis for alcoholism underlines a drastic discrepancy in our specialized hospitals. Alcoholics are neither insane, nor primarily physically ill. Therefore, special hospitals are necessary for them. Their large numbers and the need for specialized treatment and follow-up not only make separate institutions desirable, but economically feasible as well. The saving in human values would be equalled or exceeded by a corresponding decrease in the cost of public and private charity, exacted by the alcoholic from a reluctant community.

The goal of treatment is permanent abstinence. Once an individual has become an alcoholic, he can never again become a social drinker, because for him alcohol has become a drug with strong habituating potentiality, and one drink is enough to arouse dormant desires. The alcoholic has no choice between abstinence and uncontrolled drinking. For the good of all

concerned, it is best that the therapist, too, be a total abstainer. "Do as I say and not as I do" is an awkward position for the clinician. Every patient presents an individual problem and the treatment approach will be based on this and the interpersonal relationship of patient and physician, so that in the initial stages the psychiatrist is a crutch to take the place of alcohol for the personality.

The initial series of interviews with the patient should determine the method of treatment (if he is acutely intoxicated, this follows detoxification). It must be decided whether the patient can best be treated in a: (1) mental hospital; (2) specialized alcoholic institution; or (3) as an outpatient by office visits. The psychiatrist can be materially assisted in this decision by a careful appraisal that includes such psychological tests as the Rorschach, the Thematic Apperception, the Wechsler Bellevue, etc., in addition to the usual procedures of life history and neurological and mental status surveys. Regular visits or interviews are employed in which distributive analysis and synthesis allows the patient to ventilate and learn how to objectify his underlying strains and tensions. This can best be carried out by following a daily routine (self-imposed if possible, but imposed nevertheless), and the development of new insights, values, interests and amusements. These are aided especially by the socializing effect of a farm or hospital group. The nature of the patient's drinking problem is explained and discussed with him, utilizing all possible avenues of approach including dreams, specific examples from his own life history, childhood memories, present conflicts and past failures and successes. Psychological mechanisms and modes of adjustment are explained, and the fundamental facts of interpersonal relations and mental hygiene indoctrinated.

The time necessary for the initial reorientation of the personality depends primarily on the degree to which the patient's personality has been damaged. It will range from two weeks to thirty months, with a probable average of six months. Another vital factor is the organic deterioration of the patient, which, if well advanced, will often be an insuperable bar to therapy. The cooperation of friends and relatives can be invaluable in reinforcing the suggestions of the therapist and in providing a somewhat sheltered environment in which the

fledgling can try his wings without too great temptation.

When the patient has reached a level of emotional maturity which will enable him to live a relatively efficient, productive, and contented life, with kindly, tolerant personal relations and enough inner poise and stability to replace the former perpetual state of conflict and instability, he will be considered ready for a return to society. As in any serious physical disease such as tuberculosis, the cure depends on the patient's general mental and emotional health. He will, for example, be encouraged to carry candy to satisfy the bodily "hunger" for alcohol when he gets tired and jittery. A complete guide for the reeducation of the drinker has been published elsewhere.¹ It will be necessary, finally, to submit to a lifelong follow-up so that any incipient indications of relapse can promptly be nipped in the bud.

Sooner or later, if the patient is to be considered cured, it is necessary to return the ex-alcoholic to a life situation. It is here that we have made the least progress, for in many cases the patient will not be able to withstand the temptations, stresses and strains of modern, high-pressure, competitive living. To continue an analogy, it is comparable to sending a recovered T.B. patient back to his slum environment. The solution here lies in great measure in the hands of politicians, economists, and sociologists. Security must become a keynote of our future society if we are to destroy our present alcoholic 'climate'. This would include:

1. Economic security by means of increased minimum wages, a ceiling on hours, and a job for all who want to work.
2. Increased provision for wholesome recreation that can be participated in by the family as a unit.
3. A housing program that will provide a wholesome and stimulating environment for a family unit.
4. Legislated restricted hours of sale of alcoholic beverages and restriction of sale to minors.
5. A legislative control of such advertising as appeals to increased drinking.
6. An active program of education by social agencies to broadcast the danger of alcohol and the reconstitution of these agencies to

act as diagnostic and preliminary treatment centers.

7. Increased educational opportunity for the economically underprivileged.
8. An active research program in the causes and cure of alcoholism.

With all our efforts, we shall be unsuccessful if we do not destroy the legend of the "romance of alcohol."² This legend, so diligently propagated by our liquor advertisements, and so innocently indoctrinated by our novels and photoplays, portrays alcohol as an inevitable concomitant of "gracious" living and an absolute necessity if one is to be considered a sophisticated or up-to-date member of society. Drinking and having a good time, drinking and smart living, drinking and style, drinking as a sign of conspicuous spending, drinking as a sign of good fellowship, are all being drummed into the American mind by radio, press, magazine, and billboard. Addressed to emotionally mature adults, such advertising would be comparatively harmless; addressed to immature youth, boys and girls still in their teens, it produces a yearning for the romance of alcohol. Youth hears the repeated shibboleths concerning alcohol: liquor increases sexual potency, liquor is just the thing to pep you up, liquor is absolutely necessary to have a good time. The inevitable result is wholesale drinking among boys and girls too immature to withstand its allure, and to the early development of a tragic addiction to alcohol. This is the problem which the social agencies of the nation must face as their primary objective in the control of alcoholism.

AMERICAN PSYCHOLOGICAL ASSOCIATION, INC., THE.—The American Psychological Association is the natural scientific organization of professional psychologists in the United States. It was founded on July 8, 1892, and is therefore the oldest professional society of psychologists in the world. On that date, G. Stanley Hall of Clark University, George S. Fullerton of the University of Pennsylvania, William James of Harvard University, Joseph Jastrow of the University of Wisconsin, George T. Ladd of Yale University, James McKeen Cattell of Columbia University, and James Mark Baldwin of the University of Toronto met at the home of the first named and decided to organize the Association. This group constituted themselves a committee to determine the place, time, and program for the next meeting and to report a plan of organization at that time. This preliminary meeting also elected an additional 22 psychologists to membership. By the end of 1892 there were only 19 psychological laboratories in America. Of these, four were opened that same year, two the year before and four the year before that. Hence this initial membership comprised practically the entire group of professional psychologists in America.

From the beginning the object, as stated in the first and all subsequent constitutions and by-laws, was "to advance psychology as a science." In the early years of the organization this purpose was accomplished by the holding

of an annual meeting, during the Christmas holidays in earlier years and more recently early in September. At these meetings scientific papers were read by the members and by invited guests. As the Association membership increased and when it assumed responsibility for the publication of a number of scientific journals, the necessity for incorporation became apparent and this was accomplished under the laws of the District of Columbia in 1925.

The membership grew steadily from the beginning, reaching approximately 170 by 1905; over 300 by 1915; and 858 full members in 1944. The standards for election to full membership have been very high during the last decades and require, as a minimum, a Doctor of Philosophy degree in Psychology plus "acceptable published research of a psychological character beyond the doctoral dissertations." This last phrase has been variously interpreted by the Council of Directors but has usually been interpreted as two major studies beyond the dissertation. Indeed the qualifications for full membership in the American Psychological Association have been so high that such election automatically qualifies the individual for Fellowship in the American Association for the Advancement of Science.

Because these qualifications for election were so high and could not be met by such a large number of younger psychologists, many of whom were going into clinical or industrial work with little chance of publication, in 1942 these research qualifications were amended to include "five years as Associate subsequent to the granting of the doctoral degree plus evidence of acceptable contribution to psychology." Hence recognition was given at that time to work in the applied fields rather than solely on scientific publication.

Earlier, in 1925, a class of Associates was voted with the following minimum requirements: "at least one full year of graduate work in psychology in a recognized graduate school and who, at the time of application are devoting full time or graduate work that is primarily psychological, or be persons with the degree of Doctor of Philosophy, based in part upon a psychological dissertation and conferred by a graduate school of recognized standing, or be scientists, educators or other distinguished persons whom the Council of Directors may recommend from sufficient reason." The follow-

ing year nearly 100 individuals were elected to Associateship and the number has increased very rapidly and steadily to a total of over 3,800 in 1944. Associates have all the rights and privileges of Members except the right to vote at the annual business meeting.

In 1922 the Association purchased, from the Psychological Review Company, five journals: *The Psychological Review*, *Psychological Bulletin*, *Journal of Experimental Psychology*, *Psychological Monographs*, and the *Psychological Index*. This latter was subsequently discontinued in 1900. In 1927 the *Psychological Abstracts* were started under a subsidy from the Laura Spelman Rockefeller Foundation. In 1926 the *Journal of Abnormal and Social Psychology* was acquired by gift from Morton Prince. In 1942 the *Journal of Applied Psychology* was acquired by purchase. Hence the Association now publishes seven scientific psychological journals. These are edited by an elected Editorial Board with one editor for each journal and the policies are determined by a committee composed of editors, members of the Council of Directors and the Business Manager, who always has been the Treasurer of the Association. The *Psychological Abstracts* have been distributed free to all Members and Associates from its beginning and, more recently, the *Psychological Bulletin* as well. For many years, the Association has published annually a *Year Book* containing the names and professional data of all Members and Associates.

The core and real purpose of the Association has been the annual scientific meetings. One of the features of these meetings has been the Presidential Address. The list of Presidents of the Association is far too long to give in this place, but it includes the names of most of the distinguished American psychologists. Actually several scientific papers were read at the preliminary meeting at Clark University and a regular program of 12 such papers was organized for the first regular meeting of the Association at the University of Pennsylvania on December 27, 1892. In 1940 a total of 180 papers appeared on the program. Such meetings have been held annually until 1942-1944, when the scientific programs were eliminated because of war conditions, although business meetings were held in those years. A program for the 50th Anniversary Meeting at Harvard was planned but was finally cancelled for this

reason. The meeting in 1929 was also eliminated and became part of the International Congress of Psychology held at Yale University in the summer of that year. A total of 34 meetings were held at Eastern institutions, 16 in the Middle West and one on the Pacific Coast and one in Canada.

An analysis of the subject matter of the papers presented on the programs shows a trend from theoretical and more strictly systematic experimental papers to those primarily concerned with clinical, educational and industrial applications of psychology. Joint meetings were held with the American Society of Naturalists, American Association for the Advancement of Science, the American Philosophical Association and the Southern Society for Philosophy and Psychology. In recent years, the American Association for Applied Psychology, the Psychometric Society, and the Society for the Psychological Study of Social Issues arranged their meetings at the same time and place as the American Psychological Association. A number of symposia on a variety of subjects were arranged from time to time; round-table discussions were introduced in 1913 and for several years there were special sessions for the presentation of papers by graduate students. Attendance at the annual meetings has always been good compared to the size of the membership. In 1940 the record attendance of more than 1,200 persons was registered.

With the growing interest in work in the applied field, a Section of Clinical Psychology was adopted in 1919. Three years later the Association authorized the certification of clinical psychologists but so few psychologists asked for such certification that the scheme was discontinued in 1927.

The Association is directly represented on the Council of the American Association for the Advancement of Science, the American Standards Association, Inter-Society Color Council, National Research Council, and the Social Science Research Council. Most of the special or regional psychological societies are affiliated with the Association.

The finances of the Association have had a varied career. From the start until 1919 the dues were a very nominal \$1.00 a year. They were raised in that year to \$2.00 and in 1923 to \$5.00 a year. However \$3.00 of this latter sum was earmarked for the *Psychological Abstracts*

which were sent free to all members. In 1925 the dues for Members were placed at \$10.00 and for Associates at \$6.00. This increase was necessary to build up a reasonable working capital because the Association had assumed publication of a number of scientific journals. Before this year there had never been a surplus of as much as \$1000 in the Treasury at any time. Gradually a surplus reasonable for safe protection of its publications has been built up.

As the Association became larger and as its affairs became more and more complicated, the management of its affairs came more and more into the hands of its Officers and the Council of Directors. Democracy, however, has never been sacrificed. Officers and Directors are both nominated and elected by a secret mail ballot of the Association and, in recent years, the election has been by the preferential balloting system. Furthermore, the Directors merely recommend action to the annual business meeting which then votes in democratic fashion. The one exception to this has to do with the scientific journals where action regarding policy must necessarily be direct and made by a small informed group.

One important function of the Association has been performed through the work of its special committees. These have been appointed to cope with a variety of topics such as methods of teaching psychology, the relations of psychology and medical education, on precautions in animal experimentation, audio-visual aids, psychology and the public service, preparation of examination questions in psychology, and many others. A program committee has been charged with the organization of the papers to be presented at the meetings. A Committee on Scientific and Professional Ethics has quietly but effectively corrected any such ethical infractions by any of the members of the Association. Reports of these committees appear in the official Proceedings of the Association and, from time to time, special reports have been published and circulated among the members.

It becomes evident, from this account, that the interests of the membership followed current trends in psychology from an interest which was largely theoretical, systematic and "academic" to one which was largely practical, specialized, and applied to the betterment of human welfare. Such a trend is to be seen in the organization, in 1937, of the American

Association for Applied Psychology, which in 1944 had a membership of more than 725 qualified members. Within the Association the same trend is seen in the subject matter of the scientific papers which have appeared on the programs. It is also clearly seen in the change of qualification for full membership. Hence in 1942 a Joint Constitutional Committee was founded which was charged with the drawing up of a new set of by-laws for the Association which would again bring together all professional psychologists into a single organization. This joint committee was composed of representatives of the American Psychological Association and the American Association for Applied Psychology. They met in May 1943 and drew up a set of By-Laws which was presented to the meetings of these two organizations in September 1944 and unanimously adopted. A transition period of one year intervened before this new scheme went into effect.

It was decided to retain the name of the American Psychological Association because of the age and prestige which it carries. The object of the new organization is "to advance psychology as a science, as a profession, and as a means of promoting human welfare". It shall consist of three classes of membership: Fellows (present Members in the APA or Fellows in the AAAP or others with similar qualifications) Associates and Life Members. It is to have the form of representative democracy, in that a Council of Representatives becomes the legal body of the Association with full power and authority over the affairs and funds of the Association. This council shall be composed of Divisional, Regional, and Special Representatives, together with the Officers of the Association. A total of some 20 Divisions are contemplated, each dealing with some special field of psychological interest. Divisional representatives will be elected by the Divisions on the basis of the number of members. One Regional Representative shall be elected by the members resident in some nine geographical districts. Three Special Representatives may be proposed by the Council for special reasons. There is also provided a Board of Directors composed of four officers and six others elected by the Council of Representatives from among its own membership. A secret mail ballot is provided for all elections. Also a Policy and

Planning Board is provided and is to be elected by the Council of Representatives. Affiliations by other Societies are invited as heretofore.

One very important change is the organization of a Central Office of the Association "for the promotion of the objectives of the Association and its Divisions". "The functions of the Central Office shall include the administrative detail of the Association, the business management of its publications, issuance of the yearbook, facilitation of personnel placement, promotion of public relations, and such other general and special services as are allocated to it by the Council of Representatives and the Board of Directors". An Executive Secretary is to be employed as the administrative agent of the Association and as managing director of the central office.

By the adoption of these new By-Laws, the American Psychological Association has changed its character from a society which was essentially scientific in character to one which is essentially professional. This is entirely in accordance with the trend of interests and activities of psychologists in America. The formation of the Central Administrative Office is essential, not only because of the new functions such as personnel placement and public relations, but because the Association had already grown so large and its affairs so complicated that its administration could no longer be expected of individuals who gave of their time and energy and thought on a volunteer basis.

Sources of material concerning the American Psychological Association may be found in the Year Books published annually since 1918. Before this lists of Members were published. The Proceedings of the scientific and business meetings of the Association appeared in the Psychological Review from 1894 to 1903 and subsequently in the Psychological Bulletin.

was first introduced into the literature on animal behavior by Pavlov. Since he qualified the term by speaking of "experimental neurosis" it is reasonable to grant some liberty in the use of the term. When applied to animals below man, neuroses must be defined in terms of behavior rather than in psychic terms. In defining neuroses as a disease of the mind one automatically excludes the animal evidence and restricts the study of abnormal behavior to human cases. Neurosis defined in terms of personality change likewise handicaps the student of animal behavior. An animal may show an altered behavior in the test situation, but not out of the situation. Does failure to persist in an altered way mean that personality has not been changed? It is possible that the human being who shows a consistently altered behavior does so because he carries his worries with him. If he did not have a highly developed imagination "out of sight would be out of mind" and he then would show his altered behavior only under limited conditions. To restrict neurosis by the excellence of one's imagination seems to limit the concept of neurosis by factors which are independent of neurosis as such. At least this would be the belief of the student of animal neurosis.

If we are able to define our concepts of the abnormal in terms of behavior characteristics, diagnosis is made more objective and we gain access to a whole new field of research. In studies of human cases, research is limited to an "after the fact" analysis. The physician can go into the case history of a person and find circumstances which might appear provocative. He may go beyond this historical method by studying many cases and looking for common factors. However, both of these methods are open to critical errors. The life of any person contains many disturbing experiences and it is difficult to determine which or how many of them participated in causing the disturbance. Nor can one determine whether a given experience was disturbing because (1) the individual was susceptible to mental illness, (2) had his peculiar way of looking at life, or (3) the experience was the last straw in a chain of events. It is possible that similar stressful conditions are common to a group of neurotics, but if the same conditions also are present in the lives of well adjusted individuals, it is difficult to evaluate the apparent inconsistency in the effects

ANIMAL NEUROSES.—I. WHY ANIMAL STUDIES ARE IMPORTANT. The term neuroses

produced. Why do some and not others succumb to a neurosis producing situation if the situation is a cause of neurosis? It is also difficult to know how to group or classify provocative conditions. Perhaps a wide range of conditions are similar in effect; perhaps a specific condition is common to all, but it is difficult to isolate because so many variables are present; and perhaps a certain combination of conditions is needed. Unless factors can be independently varied scientific analysis is handicapped.

Another approach is to study the conditions under which a patient is cured. The psychiatrist may aid a person by locating an early childhood conflict. He may also give the patient sympathy and understanding as well as influence the people closely associated with him. What really cured the patient becomes a question. If the psychiatrist's theory of neurosis seemed to work, does it prove his theory is correct? To say it does is similar to saying that a headache was caused by a lack of aspirin because giving aspirin resulted in relief.

When animals are available for investigation, one may set up experimental conditions and expose animals with similar backgrounds to the same conditions. One can vary the previous backgrounds and hereditary factors and one can observe the symptoms as they appear. Likewise, one can be more objective in attempting cures. The doctor must do all he can for the patient but the animal psychologist can vary his remedial conditions and apply them differently to several groups. These are the necessary privileges which the research worker must have and only animals below man can be experimented with under these conditions.

It may be argued that data obtained from animals do not apply to human beings. Granted, some distinctions must be made. Some things are more important to human beings than to dogs, human beings live in a different kind of society than do dogs, they are influenced more by language than are dogs, and they are more intelligent than dogs. However, dogs, like men, can learn. They too can develop fears, their normal behavior can be restricted, they have emotions. If neurosis is due to conflicts or stressful frustrations, these conditions can be set up in the lives of animals. If animals below man show peculiarities similar to neurotic humans, should we suppose the symptoms have a different meaning because they appear in non-

humans? The student of animal behavior looks for reasonable similarities and considers differences in species before making his claims, and at the same time appreciates that basically all living forms are alike in many ways. The same basic laws of learning, of development, of heredity, of instinct and of memory apply to all forms and only minor adaptations must be made to have them fit a given species. If we grant that basic similarities in behavior dynamics exist in all forms, we extend the opportunity for research by adding a new source of data. Clinical and experimental data can then be used to substantiate and test theories.

II. OBJECTIVE OR BEHAVIORAL DEFINITION OF EXPERIMENTAL NEUROSIS

In the earliest case in which neurosis was claimed in the animal (Pavlov, 1927), a dog was trained to salivate whenever a luminous circle was exposed, but not to salivate when an ellipse was exposed. The circle had become a food signal, the ellipse a signal for no food. This type of problem is readily learned by dogs as well as by other animals. We speak of it as discrimination learning by the conditioned response method.

The discrimination was now pressed further by gradually making the ellipse more like a circle. When the semi-axis of the ellipse had a ratio of 9:8, the animal was unable to make the discrimination between the circle and ellipse with a high degree of accuracy. After three weeks the discrimination became worse rather than better and finally was lost altogether. At the same time the behavior underwent a change. The previously quiet animal that had submitted to the harness and other equipment needed for recording behavior now squealed, struggled and bit at the equipment. When released from the room it barked violently. Later, when tested on the more simple discriminations it was found that the benefit of the previous training was lost.

Pavlov claimed the dog showed an acute neurosis and found that some of the other dogs similarly underwent a behavioral change when submitted to the same kind of problem.

The behavior shown by the dog was contrary to expectation if we supposed that we were dealing with learning. Practice should not cause a loss in learning, and the dog should not struggle in a situation to which it had

learned to submit. In short, the animal ceased behaving according to ordinary rules and when it ceased being normal Pavlov called it abnormal. If we contend that neurosis represents a break with normal behavior there is an implication that the two conditions are basically different, and not different degrees of the same personality. This raises an important theoretical problem because ordinarily normal and abnormal behavior are considered different only in degree.

The condition which led to the break was (1) an insoluble problem; (2) bodily confinement with no avenues of escape; (3) the necessity of choosing between two stimuli which could not be ignored, and (4) continued and repeated exposure to this situation.

III. FURTHER EXPERIMENTS WITH THE CONDITIONING METHOD

Since the original work of Pavlov, a variety of further symptoms have been observed. Gantt studied a neurotic dog over a period of many years and observed the onset of abnormal sexual behavior. For no apparent reason erections with ejaculations occurred when the dog was in the presence of persons who had previously worked with him, or when given food of the type that had been used in the experiment. The behavior in question seemed to appear spontaneously and was unrelated to the problem which caused the original disturbance.

Liddell and his associates demonstrated changes in heart rate with the onset of neurosis in sheep and in pigs, and these changes were relatively permanent. In other cases he found that animals that were trained to lift a forepaw when the signal for shock to paw was given, instead of continuing to react to the signal by foreleg flexion, developed a stiffened limb which could be raised only with great difficulty. Here again it may be noted that the symptoms were not according to expectation and they show similarities to those frequently found in disturbed human cases.

Liddell believes that the essential conditions for producing abnormality are (1) self-imposed restraint which the animal gradually develops by submitting to the confining harness, and (2) the strain of waiting for the signal for punishment which inevitably and repeatedly occurs. The fact that doubling the length of the daily experimental period was followed by a neu-

rosis lends support to the second condition. The importance of self-imposed restraint is suggested by the fact that forcibly confining the pig was ineffective for developing a neurosis producing situation, whereas gradually training the animal to submit was effective.

IV. OTHER TYPES OF SITUATIONS AND ABNORMALITIES

Violent seizures can be produced in rats under certain conditions. The basic pattern consists of undirected and violent running in circles for a few seconds. This phase may be followed by a convulsion in which either the limbs stiffen or engage in clonic activity. The third stage is one of passivity in which the heart rate shows a profound drop and the animal is relatively insensitive to moulding and all forms of stimulation. The animal may remain in this condition of stupor for one to fifteen minutes. All three stages may be present or either of the last two may be absent. In case the last stage is absent a succession of short convulsions may occur.

Some strains of rats are more susceptible than others and rats with susceptible parents are more likely to show heightened susceptibility than offspring of normal parents. Drugs such as metrazol increase susceptibility and drugs such as dilantin reduce it. Likewise extreme fatigue and lowered body temperature reduce susceptibility.

Whether or not this pattern should be called neurotic behavior or a catastrophic reaction (Goldstein's term for completely disorganized behavior when stimulation exceeds the animal's ability to handle it) remains a matter of definition. Maier used the term neurotic because he believed it resulted from an unresolved conflict. He obtained the pattern most readily when the animal was driven by a disagreeable air blast to make a response to a situation it could not solve or from which it could not escape. Since mere exposure to sounds such as jingling of keys, loud hiss of air, electric bells and intense pure tones (including supersonic) also produce the pattern, this behavior has been called an *audiogenic seizure* (Morgan), the implication being that it is purely a reflex reaction to certain sounds. Exposure to an irritating sound may serve, however, as a conflict because the animal is unable to escape and in such case the sound is merely an aspect of

the conflict for a confined animal. Exposure to smoke (in mice) and electric shock used in place of an air blast to drive the rat into making a choice which will lead to punishment, likewise have produced seizures.

Whatever may be the final analysis of the conditions underlying the seizures, it is evident that the seizure represents a clear cut type of extreme abnormal behavior which is analogous to many of the convulsive disorders in man.

Another form of abnormal behavior occurs when animals are forced to continue to react to an insoluble problem. When rats are permitted to choose one of two cards in discrimination apparatus, they readily learn to choose a particular card providing one leads to food and the other leads to punishment. If, however, punishment for choosing is given at random and not in accordance with the choice made, the animal is unable to learn to escape punishment. When obtaining food depends on making choices and the chances of obtaining food or punishment are equal, the animal soon refuses to make a choice and consequently starves to death. This fact demonstrates that an insoluble problem is very unpleasant to the animal. If we now induce the animal to make a choice either (1) by blowing a blast of air on it or (2) by giving it electric shock for resisting, the animal is forced to choose. This condition may produce the seizure pattern described above or it may give rise to a behavior fixation. The fixated response is a stereotyped and stubborn reaction to the situation. Most commonly the animal fixates the reaction of choosing on the basis of position (the card on the right or left). In general, the fixated response is one which is most convenient for the animal in the particular situation.

A fixated response is different from a habit in that punishment does not alter it and it is much more rigid and invariable. It has the characteristics of a compulsion in that the animal continues to show the response even when it knows that it will be punished and that a different choice will not be punished. For example, suppose the animal has a fixation of choosing the card on its right. If we punish it for choosing a black card with a white circle and reward it for choosing a white card with a black circle, it receives punishment whenever the white circle is on the right, or fixated, side.

Soon the animal hesitates to choose this card. However, it does choose the card to the right and takes the punishment. The animal thus recognizes the punishment card but continues to choose it. The animal also practices its fixated right going response and takes punishment when the alternative is a dish of food on the left. Other evidence also points to the interpretation that the fixated response continues not because the animal does not know an alternative, but because it cannot give up the fixated response.

Here again we have a kind of response which is senseless when looked at from the outside. We do not expect the fixated response to be learned under conditions which do not favor such learning and we classify the behavior as abnormal. The fact that the above experimental condition causes some animals to develop fixations and other animals to continue to behave normally indicates that at a certain point a change in function occurs in the animal. When this breaking point is reached, the behavior must be described by other laws than formerly and it is for this reason that abnormal behavior seems senseless. However, we must recognize that it is senseless merely from the point of view of normal behavior.

The work of Masserman with cats likewise shows behavior which seems inappropriate from a certain point of view and it is at this point that he speaks of his cats as being neurotic. He trained cats to go to a box, raise the lid and feed at a sound or light signal. When the response was learned, a conflict was established by blowing a blast of air in the cat's face at the moment of feeding. Masserman speaks of a conflict between fear and hunger, the air blast serving as a fear stimulus. This technique resulted in the appearance of a variety of behavior patterns which Masserman calls neurotic. He classifies them into three categories: (1) Chronic anxiety shown in or out of the situation as indicated by restlessness, trembling, crouching and alterations in pulse and respiration. (2) Phobic responses and attempts at escape when the food signal is given. The tendency to feed is greatly inhibited and many cats starve themselves. If the animal is pushed toward the feeding box the fear is exaggerated. (3) Other symptoms such as excessive cleaning and efforts to secure fondling by the experimenter also

appear. Some develop fixations in the form of stereotyped methods of escape. Senseless behavior of a compulsive nature also occurs. For example, on the presentation of the food signal a cat might hide its head in the box without taking food, although very hungry.

These behavior manifestations correspond with many already described, but the classification as neurotic is largely suggested because the behavior is inappropriate from the point of view of learning and motivation. The uniqueness of neurotic behavior becomes apparent when we consider the following conditions which are ineffective for producing it. Placing a barrier in front of the food box prevents the animal from feeding when the signal is given, but the effect of this method is to cause the animal to cease reacting to the signal. Likewise, the animal may become accustomed to the frightening effect of an air blast and react less and less. When however a conflict is present, a group of behavior patterns occurs which do not seem to be called for by the training method.

Interesting also is the fact that cats made neurotic prefer milk containing alcohol to plain milk, whereas normal cats prefer the ordinary milk. Intoxicated neurotic cats lose some of their phobias. This fact is particularly interesting since the cats resemble human alcoholics.

Other experiments have been performed in which conditions of nervousness and frustrated behavior have been shown. The above examples illustrate the more extreme types of disturbance and the situations for producing them are the most representative for studying neurosis.

V. THEORETICAL CONSIDERATIONS

If we think of abnormal behavior as extreme degrees of normal behavior, then normal and abnormal behavior become different degrees of functions of the same behavior mechanisms. This is the usual and generally accepted view. Despite this fact behavior is characterized as neurotic when it is different from expectation, not merely more or less than of what is expected. Punishment for a response instead of lessening a response, freezes or fixates that response. A feeding signal, instead of being ignored when feeding is made unpleasant, builds up phobias and anxieties which extend outside the situation. In order to account for

results entirely different or opposite from those expected, one must postulate the introduction of added determiners of behavior, not the continuation of determiners already in operation.

In all of the situations in which marked changes in behavior occur, a stressful condition is present. Pavlov, Masserman and Maier believe conflict is present. Liddell emphasizes strain and restraint. In addition, all experiments contain an element of confinement and inability to avoid a problem. Thus, in one type of technique, a discrimination cannot be made, but the problem continues to demand a different reaction (Pavlov's method). In a maze problem which the animal cannot solve, a breakdown does not occur, but in such a case the animal brings itself to the choice situation. In Pavlov's situation, however, the necessity of a choice is imposed and the animal is confined.

In Liddell's situation, the animal must patiently wait for a punishing signal which inevitably occurs. When the series of tests is long, the problem not only becomes more stressful, but more confusing. In Maier's situation, a response which the animal has no inclination to make is forced upon it through the medium of an air blast or an electric shock. Finally, Masserman gives the food signal which through added training is a reminder of the air blast in the face and the animal cannot control its occurrence.

These observations are also supported by experimental results which deal with conditions which relieve the animal's disturbance. (1) Masserman found that cats could be cured of their neurotic behavior if they were trained to manipulate the feeding signal. (2) Discrimination problems in general, even if the animal cannot learn them, produce no neuroses but in these the animal determines when it will make a choice. (3) Maier found that conflict situations in which convulsions occur are less effective if the animal is free to make an abortive or substitute reaction to the conflict situation. Also the appearance of a fixation reduces the nervousness of an animal and makes it respond more readily to a frustrating situation. The fixation does not solve the problem but it gives the animal a stereotyped reaction which it can use in the situation, thus making choice unnecessary. Guiding the animal into a correct

response also relieves the animal of facing a choice which is imposed and this method readily cures fixation, although it is ineffective for teaching the same animal anything new.

It appears that when an organism is persistently driven into making a choice it cannot bring itself to make on the basis of preference, we place it under a strain which it cannot withstand. The responses which finally occur are likely to be violent and catastrophic and fail to show any of the characteristics which are to be expected by the motivational conditions which are part of the conflict. Great variations in individual expressions may be expected since no direction in response is specified. Species difference may occur and in all cases the responses are likely to be those which are readily accessible to the animal. Discrimination and differentiation are lost because these call for mature development and fine control, not mere accessibility. Exaggeration in behavior is a common trait because this indicates lack of discrimination. Convulsive phenomena may occur in extreme cases and convulsive phenomena are primitive reactions in that they engulf the total musculature (loss of individuality).

When we think of abnormal behavior as a break with the normal, we do not look for the same meaning in the abnormal behavior that we do when we think of it as a continuation of normal behavior. Rather, we seek to analyze the nature of the mechanisms which take over when the stimulus-situation is beyond that which the organism can handle. However, if we attempt to explain the abnormal in terms of normal mechanisms we seek for an analysis in terms of a motive. Often the motives are not apparent and so we are inclined to invent hidden or unconscious motives. The animal work appears to encourage the notion that much of disturbed behavior is without a motive. For the frustrated individual the behavior is more an end in itself than a means to an end. Obviously, more research is necessary before clear and precise concepts can be developed in psychopathology. The animal approach is a different approach and it raises some interesting and different notions. Eventually all sources of data must be integrated into comprehensive and unified theories.

APTITUDES AND APTITUDE TESTING.—Definition.

Aptitude is defined in various ways by different authorities. It may mean aptness or quickness in acquiring some skill or ability. It generally implies that there are constitutional, and perhaps inherited, factors to account for this quickness, because some people have practiced diligently for years under the best of tutorship and still do not achieve what others appear to acquire with far less time and effort. The terms special ability and talent are frequently used synonymously with the term aptitude. A talent or special ability for music, art, or mechanics, for instance, indicates the

possession of mental-physical factors above the average, roughly the 80th percentile. Aptitudes may differ from Thurstone's primary abilities in that (1) aptitudes may be made up of clusters of abilities and (2) primary abilities are considered to be mental, while aptitudes may be a combination of physical and mental factors. There is a great deal of overlapping between the two concepts, however. The most common aptitudes are considered to be musical, artistic, mechanical, mathematical, clerical, medical, legalistic, dancing, or some such ability or skill involving specific clusters of abilities which in some central aspect are relatively free of overlap from one another. General mental capacity or intelligence may be considered an aptitude, although it is not so considered in this discussion. Intelligence tests usually find a place in any test battery since if two people are equal in aptitude score, one may still be superior to the other because of superior mental ability. For the same reason personality and physical tests may be included and may, in some instances, be the basis of an aptitude. Selling ability, for instance, is frequently considered to be associated with an extroverted personality.

Theory. The concept that individuals differ from one another underlies all theories of aptitude testing. The difference may be inherited or acquired, congenital or post-natal, physical or mental, or any combination of these factors. Any factor or group of factors which accounts for variations in achievement, when opportunity for training is held constant, is a possible basis for aptitude. One investigator, Spearman, believes that the individual aptitude consists of some unique (1) nerve condition or nervous organization, (2) muscle strength, kinesiologic sensitivity, or accuracy, (3) glandular condition, or (4) combination of these three. In more cases than not, the factors responsible appear to be inherited because (1) they appear early in life without opportunity for practice, (2) the differences observed are greater than can ordinarily be accounted for through environmental influences, (3) some persons never are able to achieve a high level of achievement even with years of diligent effort, (4) equal training generally increases rather than decreases individual differences, (5) the aptitude has a stability or permanence which indicates a constitutional basis, and (6) physical factors are fre-

quently found which actually or presumably account for the aptitude. In most cases aptitudes are not to be identified with types where one either has a high talent, or none at all. The ability exists as a continuum from some zero point through all intermediate degrees to the highest possible degree.

Aptitudes are looked upon in three different but related ways with respect to constitutional organization. (1) Spearman's two-factor theory would divide the ability first into a general factor (*g*), and second into a specific factor (*s*), the main distinguishing element being the specific factor since it is different from all other specific factors (*s*'s), or aptitudes. If the talent is a simple one there may be only one *s* factor, but if it is complex, as in music, there may be several *s*'s organized into clusters, sometimes called group factors. (2) Thompson, Garnett, Hull, Thurstone, and O'Connor believe only in group factors, a multifactor theory in which there is no common factor (*g*). (3) Thorndike first held a rigid *s*-factor theory which he later modified into a three factor viewpoint, the three factors being abstract intelligence, social intelligence, and mechanical intelligence. None of these theories is mutually exclusive nor do their proponents hold to them as rigidly as they did originally. In test practice they would all go about test construction in much the same way.

Thurstone has been attempting to isolate and measure the fundamental human abilities in order to find pure factors which when either taken singly or in clusters will give an inventory of all aptitudes and abilities. So far the factors of memory, number, perceptual speed, speed of judgment, space, induction, verbal comprehension, and word fluency have been found. Likewise O'Connor considers such factors as introversion, extroversion, number ability, creative imagination, structural visualization, inductive reasoning, analytical reasoning, finger dexterity, tweezer dexterity, observation, memory for design, tonal memory, pitch discrimination, and number memory, primary abilities which can be used for vocational guidance.

An aptitude test is generally characterized by the following: (1) it measures some innate ability which is relatively, not entirely, uninfluenced by training, (2) it can be given before training has even started, and (3) it predicts the degree of success one will achieve with

training (other factors being equal), or it differentiates between good and poor groups who have had equal training and motivation. Those tests which do not satisfy these criteria should not be classed as aptitude tests although it is impossible to draw a sharp distinction between them and between achievement and general ability tests.

Measurement of Musical Aptitude. Stumpf started about 1885 to propose tests of musical talent and since that time Revez, Rupp, Seashore, Lowery, Schoen, Kwalwasser, Dykema, Ortmann, and Drake have made significant contributions. This field probably offers one of the best potentialities for aptitude testing because the talent (1) exists in purer form, (2) appears earlier in life, and (3) is manifested in higher degree than in most other aptitudes. The best known tests are Seashore's six Measures of Musical Talent originally (1919) recorded on Columbia records. This set consists of three fundamental measurements of the sound wave as discriminated by the human ear, pitch (frequency), intensity (amplitude), and time (duration), one test of consonance (combination of paired frequencies), one test of rhythm (combinations of durations), and one test of tonal memory. Except for consonance, which consistently was unsatisfactory, the reliabilities ranged from about .68 to .94, either by the retest method or by the split-half, Spearman-Brown correction method. Validity coefficients measured by teacher ratings were generally low but have been as high as .53 for pitch, .50 for tonal memory, .41 for time, .37 for rhythm, .16 for intensity, and -.03 for consonance. It has shown some power also to discriminate musical from non-musical groups as well as advanced high school orchestras from those rated inferior. In 1939 the set was revised and recorded on RCA discs. The main changes were the substitution of a timbre test for the old consonance test, improvements in selection of means for making recordings, refinements in electrical transcription, and a Series A and a Series B are available. Series B is not equivalent to Series A since it is more difficult and intended for higher levels of talent. Because either Series is less than one-third the length of the original 1919 set it possesses lower reliability. If both series are given, however, most of the reliabilities are satisfactory. No study of validity of the new test of timbre has ever been reported.

Actually Seashore has always opposed the study of the validity of any of his tests, maintaining that correlating them with musical ratings or performance is unnecessary. It is argued that pitch, intensity, rhythm, timbre, consonance, and time are acoustical qualities of the musical mind which will be possessed in high degree by the person who is musical, and since accurate measurements of these qualities have been made the tests are automatically validated. It is true that each test measures quite adequately the attribute indicated by the test name, but to what degree each is important for the musician, or how well each predicts or is a measure of musical aptitude, are important topics which have not received the attention they merit. Data from outside the Seashore laboratory indicate that pitch and tonal memory are measuring important functional aspects of musical talent but that the rest of the battery fails to differentiate known musical from known unmusical groups. Until it has been shown that intensity (loudness in the 1939 set) discrimination makes a pianist or other instrumentalist play with greater appreciation and control of dynamic nuances than one who is inferior in this test, or that rhythm discrimination differentiates between those who are inferior and superior in this quality, or that timbre is correlated with tone production, or that time discrimination predicts differences in ability to accurately keep time in a functional way significant for musical accomplishment, we are unable to say how valid these measures are for testing musical talent. Factor analysis indicates that they measure some common factor, or factors, probably aural sensitivity, concentration of attention, and memory, which are valuable for the musician, but they are better measured by the pitch and tonal memory tests which account for most of the validity of the battery and the remainder of the variance is of little musical significance.

The Drake Test of Musical Memory is an aptitude test which presents 12 two-bar melodies as standards to which possible changes in key, time, or notes are to be compared. The standard always retains the same length while the number of comparisons increases with every other trial. It is easy enough for the third grade and extends in range to the advanced adult level. The author gives much evidence that musical memory is the *sine qua non* of musical

talent, the factor without which musical achievement is never more than mechanical or mediocre. It is dominant in intonation, conception of a piece as a whole, perceiving relationships in interpretation, and in such activities as conducting and composing, and in all public performances with or without benefit of musical notation. Objective and biographical investigations confirm the importance of this factor. All prodigies have phenomenal memories, as do all great musicians. Reliabilities vary from .85 to .93 when the two forms are treated as one. Each form alone has a reliability of about .75 for heterogeneous high school groups. For musical subjects this may be raised to as high as .85. Validities vary from .50 to .67 with teachers' rankings and formal examinations. A correlation of .27 is reported between years of training and test scores for a group varying in both age and amount of training. Ease and objectivity of administration are increased by using recorded material.

Other tests have been constructed by Schoen, Lowery, Ortmann, Madison, and Drake but they either are not standardized, valid, or reliable, or they are achievement tests influenced by training to an extent which makes them impractical as aptitude tests. Many other factors hitherto unexplored by tests are important in musical skills and could be brought within objective measurement. Muscular speed, accuracy, and coordination are necessary for pianists, violinists, cellists, and some other instrumentalists, as is a "God-given voice" for singers, but such tests are still to be constructed. Music aptitude tests, and other aptitude measures, are still of more value in predicting who *cannot* succeed than they are in predicting who can succeed. Without certain abilities one cannot achieve more than mediocrity, but the mere possession of high abilities does not guarantee achievement because many other health, motivating, and social factors are also involved.

Measurement of Mechanical Aptitude. Tests in this field are of three general kinds: (1) assembly, (2) perceptual, and (3) muscular accuracy and coordination. The assembly tests are represented by the Stenquist and Minnesota Mechanical Assembly Tests in which such mechanical gadgets as door bells, electric light switches, locks, pistols, and mouse traps have been taken apart and the task of the testee is to re-assemble them as quickly as possible.

Validities and reliabilities of these two tests are fairly satisfactory, both being about .75.

Of the perceptual tests, the Minnesota Spatial Relations Test is probably the best known. It consists of four boards each having 58 different cut-out shapes in which the testee is to place 58 corresponding cut-out blocks. If one cannot recognize or judge size and shape accurately he will make a poor time score. For the four boards the reliability is reported to be .84 and the validity as measured by correlations with quality of shop work as .53. However, engineering students made lower scores than liberal arts students. This rather unfavorable indication may not be as serious as it appears because the ability measured could be important in other aptitudes also, particularly in art. A paper and pencil form of the test known as the Minnesota Paper Form-Board Test (Likert and Quasha) measures the same perceptual abilities without calling upon manual or manipulative abilities. A validity coefficient of .52 with shopwork is reported. Students in engineering and mechanical courses score higher than other groups. The last four subtests of the MacQuarrie Test for Mechanical Ability are perceptual tests. The first three, tracing, tapping, and dotting, are manual or muscular coordination tests. Altogether this test seems to have about as high a validity as any aptitude test of its kind. Validities of as high as .81 with ratings of pupils' mechanical work when the subjects are unknown to the judges have been reported for the whole battery. For completeness of sampling the various abilities necessary for shop work in high school this test is superior to any other single test. Another perceptual test, which also involves a certain amount of muscular coordination, is the Wiggly Block Test by O'Connor. Although O'Connor does not consider it exclusively a mechanical aptitude test he does think it measures important abilities necessary to the engineer, scientist, draftsman, architect, surgeon, and sculptor. At the Human Engineering Laboratory at Stevens Institute of Technology, and other places, O'Connor uses this and a black-cube test as measures of primary aptitudes in engineering and other vocations in spite of the low reliabilities and validities generally reported. The only justification for this would be that it measures only one of several abilities necessary for the aptitude in question. Further objective data are highly to be desired

concerning the value of these tests in view of the number of people who are being given vocational advice and who sometimes change their whole pattern of life as a result. Cox has developed a series of eight mechanical ability tests ranging from very original and difficult perceptual tasks to rather simple manipulative tasks. It is by far the most ambitious, ingenious, and promising of all tests in this field. One series consists of complicated models which present numerous relations from which other relations are to be inferred. Another consists of cardboard diagrams each containing written descriptions of the relationships. The testee is required to answer a set of questions about each diagram which involve the explanation of the way various parts of the depicted mechanism work. A third series is called mechanical explanation and completion in which the diagrams are incomplete, the problem being to complete the diagram by drawing in parts so as to show how some given mechanical arrangement could be brought about. Reliabilities are quite high for tests of this type, being around .70 to .80 for different subtests. It has the disadvantages of being difficult to administer and score. So far norms are not very adequate and the entire set made up of aluminum costs approximately \$107.00. Most of the tests can be administered to groups, but some are individual. The author finds a unitary factor to account for all the subtests of the battery which is independent of intelligence.

The Detroit Mechanical Aptitudes Examination contains eight subtests: tool recognition, motor speed (dotting), size discrimination, arithmetic fundamentals, disarranged pictures, tool information, belt and pulley movements, and classification. Retest reliability for the seventh and eighth grades is .76. Shop ratings of mechanical aptitude correlated .64 in two independent studies. The difference in the averages of a technical compared to an academic high school was more than three times its own standard error. Other tests could be given in the category of information tests, such as the Stenquist Mechanical Aptitudes Test (not to be confused with the Assembly tests bearing a similar name) and the O'Rourke Mechanical Aptitude Test, but to call them aptitude tests is to seriously confuse acquired knowledge with inborn capacity. If an aptitude test is to be of value it must not be sensitive to differences in

training for otherwise there is little object in testing if it is assumed that everyone can acquire the skill with approximately the same amount of training.

In the third category, muscular accuracy and coordination, should be placed the first three tests in the MacQuarrie battery. Sometimes the O'Connor Finger Dexterity and Tweezer Dexterity tests are mentioned here. Finger control and coordination is required and may be important in some mechanical work. Other peg boards, performance tests, and the Minnesota Rate of Manipulation Test could be included. They all measure a muscular skill rather than a mental aptitude. The Two-Hand Test, also known as the Wisconsin Test of Engine Lathe Aptitude, requires fine coordination among the eyes and the two hands. The task is to guide a pencil which is controlled by two hand screws and thus copy a pattern placed on a platform. A correlation of .42 between scores on this test with quality of lathe work in an engineering college has been reported.

Measuring Clerical Aptitudes. Most of these tests exist in battery form and measure speed and accuracy of various tasks similar to those found in general clerical work. The General Test for Stenographers and Typists developed by the U. S. Civil Service Commission was released in 1935 for general use. In 75 minutes it samples practical judgment, vocabulary, English usage, spelling, and reading comprehension. Although not strictly an aptitude test because it overlaps with intelligence and achievement a great deal, it does have high prognostic power and the norms are particularly adequate. Correlated with efficiency ratings the validity is about .75. The Minnesota Vocational Test for Clerical Workers is a number-comparison, word-comparison checking test which is widely used. Validity is high in that the test discriminates well between the general population and groups of skilled office and clerical workers, and accountants. O'Connor has a similar test which he calls a measure of accounting aptitude. Moore (Herbert) has revised the National Institute of Industrial Psychology Clerical Test for use in America. It contains a number and name checking section and six others: oral instruction, classification, arithmetic, copying, filing, and problems. Its sampling of various clerical abilities is much greater than either the Minnesota or O'Connor tests, and on theo-

retical grounds should be more valid. However, no specific data are available on this point. Retest reliability is .87. The O'Rourke Clerical Aptitude Test, Junior Grade, has two parts: Reasoning, and Clerical Problems. The first part measures ability to read and follow directions, information, congruity and incongruity of words in sentences, spelling, and reasoning in the solution of problems. The second part measures alphabetical filing, comparison of names, addresses, and numbers, classification, and simple arithmetical computation. Validity and reliability data are not reported. The Scott Company File Clerk Test has two parts: checking and comparing data for errors and omissions, and filing numbers and names. It correlates .82 with supervisors' ratings. The Detroit Clerical Aptitudes Test is intended for ages 10 to 16, or for high school. The eight subtests measure rate and quality of handwriting, rate and accuracy in checking, arithmetic fundamentals, motor speed and accuracy, commercial vocabulary, disarranged pictures, classification, and alphabetizing. Correlations of .56 with bookkeeping, .37 in shorthand, and .32 in typewriting are reported. Retest reliability is .85. The most common criticism is that it is more of an intelligence and speed test than a clerical aptitude test.

Measurement of Art Aptitude. No analytical study has been made so far to determine the constitutional nature of art ability. It probably consists of several abilities in unequal degrees, with one or two being dominant. The McAdory Art Test is a judgment test consisting of 72 plates, each containing four illustrations which are variations of the same object, such as furniture, utensils, clothing, architecture, painting, shape and line arrangements, dark and light masses, and color. The testee is required to rank the four objects on each card in order of merit. The criterion is the consensus of opinion of several recognized artists, art critics, and art teachers. No practical validity coefficient has been reported. Reliability averages about .85. Another judgment or appreciation test is the Meier Art Judgment Test, a revision of the Seashore-Meier Art Judgment Test. The principle is that of paired comparisons in which there are 100 plates each containing two pictures of the same painting. One of the pair has been altered slightly from the original masterpiece in such a way that it is universally judged

to be inferior by recognized artists. Validity is controlled by (1) a critical reaction by 25 art experts, and (2) by a 60-90 percent preference by 1,081 subjects. Whether any judgment test is capable of measuring an ability to perform or not is open to doubt. In the musical field, at least, the relationship is not necessarily high, or if it is high it may not be reciprocal, that is, high ability will be significantly correlated with appreciation, but high appreciation may not be nearly so highly correlated with superior functional ability. The Knauber Art Ability Test consists of 17 "Problems" as follows: (1) copying from memory a design exposed for one minute, (2) drawing Santa Claus from past memory only, (3) copying a small design by enlarging it to fit a space $2\frac{1}{2}$ times larger, (4) drawing a table in a given space without benefit of a design, (5) drawing a cup in saucer same as in 4, (6) drawing three trees, a cottage, a path, and anything else desired in a given space, (7) drawing a church at foot of mountains to give a feeling of reverence, (8) detecting misplaced or incongruous details in a series of six drawings, (9) filling in shadows in two unshaded pictures, (10) filling in one geometrical and one pictorial design each with shadings appropriate to the masses, (11) drawing a monogram in a circle and (12) also in a triangle, (13) ingenuity of design, (14) imagination in geometrical design, (15) changing a given drawing of a man to represent a different character from the one given, (16) drawing a "homeless dog" for ability to express an emotional idea, and (17) drawing something symbolic to represent labor. The test is very complete and takes about three hours to take. There is no doubt about its value as an achievement test, but to what extent it is an aptitude test is not clear. It differentiates between art majors and non-art majors and between art teachers and non-art teachers with great decisiveness, but this could still be largely on a training basis, the same as any achievement test. If it could be demonstrated that at least 50 percent of the score variance is due to innate ability this would still be a fair aptitude test except that one must be able to draw quite well before he can even take the test. Retest reliability is over .90. The Lewerenz Tests in Fundamental Abilities of Visual Art measures (1) recognition of proportion, (2) originality of line drawing, (3) observation of light and shade, (4) knowledge of subject matter, (5)

visual memory of proportion, (6), (7), (8) analysis of problems in cylindrical, parallel, and angular perspective, and (9) recognition of color. These items appear to sample judgment, appreciation, information, and aptitude factors in unknown amounts. A correlation of .63 was obtained with grades for 42 art students. Retest reliability is .87. The Selective Art Aptitude Test by Varnum not only attempts to measure talent for art in general but also to specify what field of art one has aptitude for. The test is divided into three parts, called Groups. Group A measures fundamental abilities through three tests of acuity of vision, color harmony, and tone gradations. Group B measures sensitivity through two tests of proportioning and balance and rhythm. Group C measures creative ability through two tests of speed under creative stimulus, and creative imagination. The test is still in a tentative stage and the manual needs a thorough revision to make it either intelligible or useful. No validity coefficients are given but validity is discussed over several pages by citing individual cases or small groups, and presenting statistical tables which are not very meaningful. If its validity can be established it should be a most useful prognostic test because it does not draw heavily upon actual achievement in drawing. Reliability is somewhat low, .66 to .83 for the whole test, split half method, corrected. It is not significantly related to intelligence or to the Mcier-Seashore Art Judgment Test.

Measurement of Shorthand Aptitude. The Turse Shorthand Aptitude Test contains seven parts known as stroking, spelling, phonetic association, symbol transcription, word discrimination, dictation, and word sense. It can be given before one has started the study of shorthand and has a correlation of .67 with a standardized achievement test in shorthand. Split-half reliability is over .90. The Bennett Stenographic Aptitude Test consists of two parts, a learning substitution section and a section of misspelled words to be identified and respelled. It can be given before one has started the study of shorthand. A biserial r of .27 with grades in a secretarial school was obtained with the substitution section and .48 with the spelling section. Reliability coefficients are .97 and .91 respectively. Part of the power of this test is due to its overlapping with intelligence to the extent of r .27 for the first section and .62 for the second section, as measured by the Army Alpha. It is also

an achievement test due to the spelling section although the same correlation is reported (.47) for experienced as for inexperienced (practiced) groups.

Measurement of Medical Aptitude. The Moss Aptitude Test has been used for more than a decade by members of the American Association of Medical Colleges. It consists of six parts called (1) comprehension and retention, in which a difficult paragraph from a medical text is presented to the testee to read and study for 15 minutes after which he is given a true-false test on the content, (2) visual memory, in which some detailed anatomical diagram is shown the testee for 15 minutes after which he is given another similar diagram and required to fill in the missing labels, (3) memory for content, (4) logical reasoning, (5) scientific vocabulary, and (6) understanding printed material. A new form is published each year. It will be seen that this is not strictly an aptitude test since it is largely a generalized learning test for difficult material. To a large extent it is an intelligence test, and in some ways it is an achievement test for premedical material. When test scores are compared to medical college grades it has been found that only five per cent of those in the highest decile failed, while thirty per cent who scored in the lowest decile failed. When test scores were compared to ratings of internes it was found that those who scored above 200 on the test received an average rating of 1.8 on a five-point scale, while those scoring below 100 received an average rating of only 2.3. Correlations are not given but it is doubtful if they would be over .50 for such data, which is fair but not good for a validity coefficient. Reliabilities are not given. The test is not available for general use but is sponsored by the American Association of Medical Colleges and given only to those who expect to apply for admission to a medical college. The test results are not made available to the testee.

ASPIRATIONS, LEVELS OF.—In recent usage, level of aspiration usually designates goal-seeking behavior of the type where behavior operates under cognitive influences. More rarely the term refers to behavior involving uncomplicated forms of *felt* urges and drives. For the former sense of the term, as with "ambitions" in general, drives are modified by such factors as the subject's estimate of his own capacities, his knowledge of the attainability of the goal, and other potentially cognitive factors.

Beginning with F. Hoppe's initial studies, a fruitful and growing amount of experimental work, chiefly that of K. Lewin and his associates, has been devoted to this area. Such research has been directed chiefly to the study of the *quasi* and somewhat artificial needs resulting from an experimentally formulated *Aufgabe*. Quasi-needs are typically less intense than the real and more permanent needs of the subject. It is argued that weaker needs still follow the same laws as stronger ones, to the point where increased strength induces structural changes of personality. Hence, research on quasi-needs should yield sound and practical information in the field of motivational psychology.

Some of Hoppe's chief findings were: that the subjects' experiences of success and failure are consequences, not so much of the absolute goodness of the performance, but rather of attainment or non-attainment of the level of

aspiration. Subjects tend to lower or raise future goals depending on their successes and failures with previous goals. Experiences of success and failure do not attend tasks which are too easy or too difficult. Hoppe inferred that levels of aspiration are chiefly determined by two sets of opposing principles in the individual: (a) *ego* forces which tend to set high goals even at the cost of failure, and (b) *pleasure* principles which seek successes, thus lowering the aspiration level.

Since Hoppe's work, research has been directed towards (a) improvements in experimental techniques, and (b) the attainment of quantitative measurements of levels of aspiration and performance, and the correlation of such measures with various aspects of personality and behavior.

Experimental Techniques. An important endeavor has been to select tasks in which level of aspiration, change of level, and goodness of performance are measurable in terms of the same units (J. D. Frank). The other important phase of development of procedure consists of attempts to define and control situational and personal factors involved in research. Discussion of the latter aims is covered in the following review of the conditions and correlates of aspiration.

Conditions and Correlates of Aspiration. As regards field conditions, the effects of barriers and frustrations have been given leading attention. Variant forms which barriers may take are defined (see K. Lewin and H. F. Wright). Objective field barriers are distinguished from social (prohibitions, customs) and personal barriers (dislikes, scruples, etc.). *Means* to an end may be regarded as true barriers, and barriers may be regarded as means to an end. Barriers are such only so long as they can be overcome—beyond this point they become field-limiting factors (Lewin), resulting in the cessation of striving or in substitute responses. Experiments (of Wright and others) are offered to indicate that barriers tend to enhance personal positive valences (attractions) even where equivalent goals with less barrier are available. However, where subjects make selections for others the line of least barrier is pursued, unless there is identification between the subject and the person whose goal-objects are being selected. The principle of parsimony (use of the means with least barrier) thus tends to cancel the effects of

barrier-enhancement, and becomes prominent when alternative goal-objects and means towards them become identical. Satiation tends to neutralize valence-enhancement due to a barrier. Barriers to goals tend to enhance attendant memory traces (Zeigarnik and others).

Theoretical attacks on the question of the mechanisms of barrier-enhancement of goals are on record. One view (Wright) holds that any goal-object releases energies which accumulate in situations involving barriers—the subjective correlate is that of a growing attraction of the object. It is possible that valence-increase is relative—that the object with least barrier may decrease in valence rather than that the object with greater barrier shows valence increase. Another view (H. Lundholm) holds that barriers cause means-energies to drain to other organic areas resulting in emotional intensification and hence increased awareness of the desirability of the object. Barriers causing the experience of frustration are assumed by many to generate emotional states (Conflict theories of emotion—John Dewey, F. A. Hodge, C. W. Darrow). An alternative solution of situations involving strong frustration is to resort to substitute activities, such as sublimation, transference of affect, displacement, regression, vicarious satisfaction (K. Lewin, M. Henle).

Various traits of personality have been studied as correlates of aspiration level and derived concepts. Thus, excess of aspiration level over performance is moderately associated with narcissism, aggression, emotionality, introversion (J. D. Frank). Significant and practically useful relations between reaction to frustration and academic achievement are suggested (R. P. Fischer).

ATTENTION.—Attention, for the psychologist as for the layman, designates a group of phenomena that center around selection of objects and aspects of objects and of memories.¹ Of all the sensory stimuli that present themselves and of all the memories that might be suggested only one is noted. When several stimuli combine to form an object, one will be more clear than the others. The phase or object that will be noted varies from moment to moment. The attention experience also includes the contraction of muscles which give rise to sensations of strain. These contractions arise automatically at the time of vigorous strivings, as in lifting a weight, in making a serious decision, or in holding one's self to a task when tired or attracted by a more pleasant activity. The incidental strains have popularly been taken as an indication of activity and called effort. On the other hand when attention runs smoothly a feeling of pleasure is present. This is usually called interest and is sometimes confused with attention or regarded as a cause of attending.

While it is universally appreciated that selection is always present, some have questioned recently whether the process is unique enough to deserve a separate name. The various elementary processes assigned to attention have been separated and grouped in different ways. One fairly recent grouping of this kind has been made by the Gestalt psychologists. They are most struck by the alternating clearness of different phases of an object. Objects of ambiguous perspective, such as three steps with little decrease of size in the upper and lower lines can be seen either as steps or as a projecting cornice. Figures of irregular outline in massed black and white may be seen either as white on a black ground or as black on a white ground. Studied for a time the perspective interpretation of the lines will shift regularly, the near parts will retire and the far parts approach and vice versa at regular intervals. Similarly the white parts of

the figure in black and white may be prominent at one time and the black portions at another. Rubin gave the name of "figure" and "ground" to the two parts, and spoke of "becoming the figure" as the equivalent of clearing up in attending. Following this usage the Gestalt school regard attending as a change from ground to figure, and would use figure and ground as a name for the selection process. Linguistically this is inconvenient for no one, not even the believers in the theory, speak of figurizing as a substitute for attending.

Wittenborn¹ has demonstrated experimentally and statistically that a group of elementary factors exist that agree with what is popularly called attention. He gave 175 men certain of the standard tests that involved continuous effort with strain. He also gave the same men certain tests that he prepared himself. The new tests required recognizing certain successions of numbers and letters as a series was presented. He applied to all his results the Thurstone methods of factor analysis and found that two of his own tests were specially loaded with the attention factor. Others of his own and standard tests showed a slighter loading. This statistical treatment indicates according to Wittenborn that attention should be counted among the simple factors. He regards continuous effort as the phenomenal characteristic most prominent in the attention complex. The method reinforces direct observation in demonstrating the presence of a group of phenomena corresponding to what is popularly known as attending.

The more important phenomena in the attention group that have been measured are the range of attention or the number of objects that may be appreciated simultaneously, the duration of attending, or the length of time that a single stimulus may be held clear, and the effects of distraction. Measurements of the range of attending were among the first made. Jevons and Hamilton made crude measurements early. Cattell devised the tachistoscope to give a brief exposure of designs on cards. Results show that there is an increase in the percentage of correct enumeration as the number of items decreases. With four dots near 100 percent correct responses are given. The more complicated the objects the fewer can be enumerated. Objects with meaning can be reported

more accurately than meaningless material. Almost as few errors are made with short words as with dots or single letters. Assuming that 50 percent correct answers is a measure of the number that can be seen, results of three investigations indicate that the range of attention varies between 6.2 and 11.3. Grouping simple objects increases the number that can be seen. Almost as many triangular groups of three dots can be seen as single dots. Letters arranged in small words are seen more accurately than the same number of single letters. Observation of the procedure in observing indicates that the number of items that can be seen depends upon the memory after-image. The objects persist for a second or so after the exposure and they are counted in this image.

The length of time that an object may be attended to has been studied for faint stimuli by a method similar to that used in the work on figure and ground mentioned above. If faint gray lines are produced by rotating a disk with a series of small squares extending from the center to the circumference of the disk, a ring may be chosen that will be seen for a time and then disappear. These fluctuations are regarded as due to changes in the efficiency of the visual mechanism. The complete cycle ordinarily has a length of from one to five seconds. The relative lengths of the periods of visibility and of invisibility varies with the distance of the particular equal squares from the center. The more distant from the center, the greater the proportion of white to black. The fainter the stimulus, the shorter is the period of visibility. It is probable that the periods recorded are longer than the real wave because some shifts are overlooked. Each record also involves two shifts—one the real shift, the other the shift from the disk to the act of recording. Billings, recording all shifts, found an average of about a second from one point of maximum clearness to another. On occasion the shifts came as close together as 0.1 sec. to 0.2 sec. The minimum approaches the refractory period of the nerve. These fluctuations appear in listening to faint sound, in the alternate interpretations of ambiguous perspective, in the alternate dominance of the two eyes when each is stimulated by contrasting colors, and according to Bills in the efficiency of motor work.

Distraction is the supposed reduction in efficiency as a result of a second stimulus or activ-

¹ Wittenborn, J. R., "Factorial Equations for the Tests of Attention," *Psychometrika*, 1943, 8, 19-35.

ity. Experiments show that the effect of a second stimulus is the reverse of that assumed, since the second stimulus increases rather than decreases the efficiency of performance. If a loud sound is given when one is adding, adding is quicker and more accurate on the average than when silence prevails. Morgan and Ford recorded the strength of incidental movements during adding with and without the noise and found that muscles contract more strongly during the sound and relax when it ceases. They have urged that this means that greater exertion of the body-mind processes is present during a distraction, and more effort than is necessary to overcome the distraction, so that more is accomplished with than without the noise. It is probable that the increased performance is at the expense of greater fatigue. Studying while listening to the radio may be more effective while studying dominates, but the average performance is reduced by the period when the radio dominates.

The antecedents of selection or of the increased clearness of different classes of material give some indications of the cause of attending. Most frequently mentioned and probably most important for theory is a task that has been set for the observer or one that he has set himself. If one has been asked to mark the verbs on a page, one will have no idea of what has been said by the words. If one is asked to say which is the higher of two tones and then later is asked which had the greater duration, he will not be able to say. The task may be set by one in authority or may be suggested by what has gone before. When the questions arise from the context, they may be specific as a definite question for which an answer is sought or may be more general. If general they prepare to see anything in a class. Hunger leads one to look for a restaurant sign or to smell food of any kind. A remark about art will lead one to notice paintings on the wall. In the ordinary course of the day one task suggests another, so there is a continuous ordered series of problems that controls behavior logically.

The purposes or tasks themselves are organized by experience and education. This gives earlier training an influence upon what shall be selected. Many of the more fundamental tendencies to attend go back to the modification of the nervous system in the evolution of the race. One is alert to all objects that may affect the

survival or well being of the individual, to water when thirsty, to a moving or changing object at all times, to harsh tones or threatening gestures, to members of the opposite sex and so on. These may be called the conditions of attending. The inherited ones go back to the nervous system. Animals that develop nervous systems that respond preferentially to objects that are dangerous or especially beneficial survive in greater numbers and tend to transmit the change to their progeny.

A word may be given to the question of the need for attention as a word or concept in psychology. If one means by attention a force or any kind of entity, then the answer would be no and the same answer would be given for the need of memory, emotion, will, perception and the rest. If one thinks of the concepts as convenient points of reference for a group of related phenomena, one can answer that the term is convenient for reference to a group of events, that have much in common in their conscious quale and in the function that goes with them. The objection to such terms is found in the tendencies to assume that a single cause or faculty lies behind them or that each constitutes a single entity. One is bound to deal with such groups of experiences as units and a word to designate them is bound to develop. The scientist must become accustomed to avoiding implications of entities. Thus attention can be used to designate the selective phenomena of consciousness and the differences in clearness of objects, as well as the narrowness of the range and the alternations in clearness. One must avoid assuming that attention is a force that produces these changes. On the factual side one can relate the changes to recent other experiences, but exercise reserve in asserting a causal relation. One can speculate that the nervous system mediates between the two groups of phenomena if one sees that present knowledge of the nervous system is insufficient to say just how.

W. B. PILLSBURY,
University of Michigan

AUTONOMIC NERVOUS SYSTEM.—

1. *Definition.* The term autonomic nervous system is used to designate the sum total of nerve fibers which supply the visceral organs with motor and secretory impulses, these organs being the glands, the smooth muscles, and the

heart. The division between the autonomic and central nervous systems is functional and not anatomical because some of its neurons lie in part within the cerebrospinal nervous system.

2. *Anatomy.* The autonomic nervous system may be subdivided into the cranial autonomic nervous system, whose fibers make their exit by way of the third, seventh, ninth, tenth, and eleventh cranial nerves; the thoracolumbar nervous system, whose fibers make their exit by way of the upper lumbar spinal nerves; and the sacral autonomic nervous system, whose fibers run in the visceral rami of the second, third, and fourth sacral nerves. The fibers of the thoracic columnar stream run by way of the side rami through the sympathetic side chain of the spinal cord, while the fibers of the cranial and sacral stream make no connection with that trunk but run directly to the peripheral nerve plexus ending in the terminal ganglia within the visceral organs. The cranial and sacral systems also agree in their response to certain drugs like atropine and adrenalin. It was therefore found desirable to group the cranial and sacral system together as the cranio-sacral autonomic system, often called the parasympathetic system, to be contrasted with the sympathetic nervous system proper, a name now applied to the thoracolumbar part of the autonomic nervous system. Most of the structures innervated by the autonomic nervous system receive a nerve supply from each of the subdivisions.

The sympathetic side chains or trunks are two large cords which extend through the neck, thorax, and abdomen, and run along each side of the vertebral column. They are composed of a series of ganglia, arranged in lines and connected by short nerve strands. These cells are connected with the spinal cord at each segment by one or more gray rami communicantes through which impulses reach the spinal cord from the sympathetic trunk. Impulses reaching the trunk from the spinal cord travel from the thoracic and upper lumbar nerves to the sympathetic ganglia by way of the white rami communicantes. Towards the periphery the sympathetic trunk gives off branches which form nerve plexuses in close proximity to the large arteries. The most important of these plexuses is the celiac plexus, found near the upper branch of the abdominal aorta, containing the celiac, mesenteric, and the aorticorenal ganglia.

There are, finally, terminal ganglia located close to or within the structures they innervate, as, for instance, the ciliary ganglion for the eyes, the cardiac ganglion for the heart, and groups of nerve cells within the walls of the intestines.

The vast majority of the functions of the autonomic nervous system are efferent functions. For some time it was doubted that afferent fibers could be demonstrated, but it is now established (Chase and Ranson, 1914; Ranson and Billingsley, 1918) that visceral afferent fibers run in the ninth and tenth cranial nerves; also in many spinal nerves, especially in those associated with the white rami communicantes; and finally in the second, third, and fourth sacral nerves. These nerves run to the viscera without interruption in any of the sympathetic ganglia.

The efferent visceral neurons are all interrupted before they reach the structures they innervate. The first neuron terminates in the sympathetic ganglia, where the nerve impulses are relayed to the periphery by secondary neurons. Langley, in 1900 and 1903, showed that there are always two and never more than two neurons conducting nervous impulses from the central nervous system to smooth muscle and glandular tissue. This could be demonstrated by the injection of nicotine into rabbits, which prevents the passage of impulses through the sympathetic ganglia. After such an injection, an undiminished response of the end organ can still be obtained by stimulation of the peripheral (postganglionic) sympathetic nerves, but it will no longer respond to stimulation of the central neuron leading to the ganglion. Preganglionic neurons start from cell bodies in the anterolateral column of the spinal cord. The fibers have a myelin sheath. They run through the cerebrospinal nerves to the sympathetic trunk, and terminate in its ganglia. The postganglionic neurons start from cells located in these ganglia and axons, remain for the most part unmyelinated, and make up the sympathetic nerves and plexuses to and in muscle and glandular tissue.

There are, then, three kinds of fibers in the autonomic nervous system: (1) preganglionic efferent fibers of small size and myelinated, terminating in the sympathetic ganglia; (2) postganglionic efferent fibers, mostly unmyelinated, terminating in involuntary muscle and glandular tissue; and (3) visceral afferent fibers,

containing both myelinated and unmyelinated fibers, connecting the cerebrospinal ganglia and the viscera. The chief pathways of efferent innervation of the viscera are as follows: contraction of the pupil and accommodation are furnished by the craniosacral division via the ciliary ganglion; dilation of the pupil is effected by the thoracolumbar division via the superior cervical ganglia and the internal carotid plexus. The salivary glands are stimulated to secretion by fibers from the craniosacral division through the seventh nerve and chorda tympani; while the secretion is inhibited by fibers from the thoracolumbar division via the superior cervical ganglion and plexuses on the external carotid artery. The heart is inhibited by fibers from the craniosacral division through the vagus nerve and accelerated by the thoracolumbar division through fibers via the cervical and upper thoracic sympathetic ganglia. The stomach is excited to peristalsis and secretion by the craniosacral division via the vagus nerve; it is inhibited by the thoracolumbar part through sympathetic fibers via the celiac plexus. The bladder is excited to contraction and to relaxation of the sphincter by the craniosacral branch via the second and third sacral nerves. The sphincter is contracted for the retention of urine by the thoracolumbar branch through sympathetic fibers via the inferior mesenteric ganglion.

The blood vessels, particularly the small arteries of the skin and skeletal muscles, are innervated solely by the sympathetic division. The coronary, pulmonary, and probably also the cerebral and intestinal blood vessels have an additional nerve supply from the parasympathetic division, the latter being dilator, the former constrictor. Removal of sympathetic fibers results in marked dilation of blood vessels of the skin with rise in skin temperature. Sympathetic excitement leads to blanching of the skin and fall in skin temperature. A striking shift in circulating blood from the visceral to the peripheral area occurs during vigorous muscular exercise and after severe hemorrhage.

The sweat glands are innervated by sympathetic postganglionic fibers. Sweating commonly accompanies peripheral vasodilation for the purpose of heat loss, but it may also occur with vasoconstriction (cold, clammy hands). The sudomotor sympathetic fibers in contrast to vasomotor fibers, are cholinergic.

The endocrine glands are under direct control by the autonomic nervous system. In addition to the adrenomedulla excited by sympathetic fibers, the anterior pituitary gland receives sympathetic fibers through the carotid plexus and also parasympathetic fibers from the Vidian ganglion. The thyroid gland is known to have vasomotor innervation, but there is no direct proof so far of a direct secretory innervation. Parasympathetic stimuli reaching the pancreas stimulate the islands of Langerhans to secrete insulin.

The control of the respiratory system is complicated. The respiratory center in the medulla oblongata regulates respiratory rate and amplitude. It is sensitive to changes in oxygen and carbon dioxide tension and also to the influence of afferent fibers in the vagus nerve. And, finally, it is controlled through impulses from the wall of the aorta at the carotid artery (carotid-sinus reflex). The smooth muscles of the bronchial tubes receive parasympathetic fibers from the vagus nerve and become contracted through parasympathetic impulses. They may be dilated through sympathetic stimulation.

The reproductive organs receive vasodilator parasympathetic fibers for the engorgement of erectile tissue and stimulation of secretion in prostate and vagina, but the uterus seems to receive sympathetic fibers only.

3. *Historical.* The autonomic nervous system is sometimes also called the involuntary or the vegetative nervous system. Occasionally one also hears the term sympathetic nervous system, but in present usage this term describes only one part of the autonomic system. The term sympathetic goes back as far as Galen. He thought that the junction of peripheral nerves connecting the various viscera might permit animal spirits to flow from the brain to the organs and from one organ to the other. This to him explained the fact that in case of disease of one organ, symptoms often appear in another part of the body also: suffering with one another.

The Danish anatomist Winslow, 1732, gave the name "grand sympathique" to the chain of ganglion cells running along the spinal cord because it seemed to bring into sympathy various remote parts of the body. Even earlier Willis, 1664, had introduced the concept of involuntary movement (of the viscera) as op-

posed to the voluntary movement of the skeletal musculature.

The term vegetative nervous system was first used by Reil in 1807. At that time, under the influence of Bichat, 1800, it was thought that the autonomic system was completely independent from the brain and spinal cord. It was supposed to be responsible for "*la vie animal*" while the brain and spinal cord were responsible for "*la vie organique*." This distinction is still preserved in our present terms of vegetative system as contrasted to somatic nervous system.

The 19th century brought the discovery of the unmyelinated structure of sympathetic fibers (Remak, 1838), of the discovery of such fibers in the walls of blood vessels (vasomotor fibers, Claude Bernard, 1851), and there followed studies of the effect of the vagus nerve on the heart and of the chorda tympani on salivation. Gaskell, 1885, finally reestablished the connection of the cerebrospinal system and the autonomic nervous system by tracing the course of non-myelinated fibers from the spinal cord to the sympathetic ganglion cells. He also postulated the existence of two opposing systems for the control of visceral motility and glandular secretions.

The term *autonomic* was first used by Langley, who in 1893 started his work on the effect of nicotine on the transmission of nerve impulses in autonomic ganglion cells. He traced the exact distribution of "preganglionic" and "postganglionic" nerves by observing whether or not application of the drug blocked the progression of impulses through a given ganglion. He used the term *autonomic nervous system* to include the outflow of nerves in the cranium, thoracolumbar, and sacral regions. In 1905, he subdivided these outflows into the "sympathetic," comprising the thoracolumbar division, and the "parasympathetic," comprising the cranial and sacral outflows, because the latter two agreed in their reaction to drugs.

Although the claim has been made that the autonomic nervous system is phylogenetically older than the cerebrospinal system, there is no embryological evidence to show that the autonomic nervous system appeared earlier than the central nervous system. Throughout the whole series of vertebrate animals, both systems appear together, function in intimate relationship, and are equally important. In human beings,

the highest functions of integration for the autonomic nervous system lie within the brain itself.

In trying to circumscribe the functions of the autonomic nervous system as a whole, Cannon came to the conclusion that in contrast to the cerebrospinal system, which deals with the outer environment (is exteroceptive), the autonomic nervous system deals with the domestic affairs of the interior of the organism as an interoceptive system. When the activity of the cerebrospinal nervous system alters the fluid matrix of the body, the autonomic nervous system, through its sympathetic division, has the function of re-establishing the equilibrium by its interoceptive functions. To this Cannon applied the term "homeostasis."

The observation that stimulation of the autonomic nervous system may bring about the secretion of powerful chemical substances led to a revolutionary reinterpretation of the conduction of nerve impulses. Cannon was able to show that sympathetic excitement is followed by the secretion of adrenalin; this substance then serves to sustain the "adrenergic" effects of the stimulation initiated in the sympathetic system. He was able to show that even at the occasion of sympathetic discharges in the visceral organs, minute quantities of a substance almost like but not quite like adrenalin, called sympathine, appeared. Dale, in 1916, supported by former experiments of Loewi, was able to demonstrate conclusively that stimulation of the parasympathetic section of the autonomic nervous system also leads to the appearance of a substance facilitating and sustaining the "cholinergic" state of stimulation. In this manner the theory of chemical transmission of nerve impulses was developed. Research interest then shifted to the central integration of autonomic activity in the hypothalamus. During intracranial surgery removing pituitary tumors, Harvey Cushing, 1913, has noticed that lesions to the floor of the third ventricle may bring about violent changes in gastrointestinal activity. Fulton and his co-workers, 1929, Ranson, 1939, and Gellhorn, 1943, worked out the precise features of this central autonomic control of visceral activity.

Observations on the role of the hypothalamus after removal of the cortex by surgery led to the theory of the hypothalamus as the central station of control for visceral activity, hence a

prime factor in emotional reactions. Indeed, it became customary to think of the hypothalamus as the central station of control for the emotions. The appearance of an explosive discharge simulating violent rage, which occurs after the removal of the cortex and which resembles the manifestations of violent rage (and therefore called "sham rage"), led Bard, 1928, to support this concept of the hypothalamus. Only recently Masserman, 1941, has questioned this view. By electrical stimulation of the hypothalamus in a living cat, he was able to show that while it is true that certain phenomena accompanying violent emotion such as panting, salivation, wide pupils, and erect hair occurred, together with biting movements of the jaws and unsheathing of the claws, nevertheless, these vivid accompaniments of emotion disappeared at the moment the stimulus stopped and the cat then went on with what it had been doing before the excitation as though it had experienced no stimulation at all. At best this stereotyped activity could only be called "pseudo-affective." Adding to this the evidence that such reactions cannot be conditioned (as is possible with true emotions), the conclusion was inevitable that the hypothalamus is not a center of emotion or of feelings of any kind. It is now conceived of as a motor way-station where emotional expression is integrated into behavior patterns on its way out into the muscles and glands (Cobb, 1943).

The latest concern, stimulated by the war, has been that of traumatic shock. The peculiar alteration in the activity of blood vessels, of visceral organs and glands as it occurs after severe injury or overwhelming emotional stimulation was studied by Cannon during the first World War and became the object of renewed inquiry in 1936 when Selye described what is now known as the "alarm reaction." It was realized that in response to a great variety of noxious agents the organism responds with the same set of symptoms. The reaction might therefore be regarded as a syndrome representing a "call to arms" of the body's defense forces.

This reaction was found to have two phases: the first called "shock" consists of tachycardia, decrease in muscular tone and body temperature, formation of gastric and intestinal ulcers, hemoconcentration, and discharge of adrenalin. After about 24 hours, this is likely to be fol-

lowed by the "counter-shock" phase. Cannon's original notion that one significant function of the interoceptive system was the maintenance of chemical equilibrium in conditions of emergency was thus validated, and opened the way for studies of great clinical significance.

At the clinical level, our knowledge concerning the autonomic nervous system is becoming rapidly more and more important for the management of psychoneuroses and of those medical diseases which are now collected under the name of psychosomatic disorders. While anxiety neuroses and depressive states present diffuse and widespread alterations in many visceral organs controlled by the autonomic system, the psychosomatic conditions present a regional dysfunction. Specific viscera are involved. We find, for instance, ulcers of the stomach, ulcers of the spasm of a blood vessel in migraine. Regulating the control of the autonomic nervous system either by altering the emotional responses through psychiatry or by altering the autonomic control through chemical agents (internal medicine) or finally by interrupting the autonomic pathways conducting disturbing impulses (surgery and neurosurgery) will be alternate methods of clinical management. A new Journal "Psychosomatic Medicine" is devoted to laboratory reports and clinical studies concerning this field of inquiry.

4. *Physiology.* In describing the physiological functions it seems well to start with Cannon's concept of interoceptive and exteroceptive systems. He summed up the important features of the interoceptive nervous system in 1932 as follows: "(1) an absorption of extra acid in the buffer substance of the blood; (2) a prompt supply of extra oxygen to burn the non-volatile lactic acid to volatile carbonic acid, which can be rapidly discharged; and (3) an acceleration of breathing so that carbon dioxide is driven away from and extra oxygen is drawn into the lungs. In short, the circulatory and respiratory mechanisms work at their maximum capacity. Once more the sympathicoadrenal system steps in to save the fluid matrix from grave disturbance. The circulatory adjustments . . . constriction of the splanchnic vessels . . . acceleration of the heart, discharge of extra corpuscles from the spleen . . . are all made by means of the sympathicoadrenal system. And, in addition, this system probably plays a role in facilitating the respiratory processes, for it can quickly and

effectively cause dilation of the bronchioles and thus reduce the frictional resistance to the to-and-fro movement of the respired air."

The role of the thoracolumbar division of the autonomic nervous system may then be thought of as an emergency system which may not be functioning all of the time but which is always ready to go into action under adverse conditions. Some of these are pain, extremes of temperature, asphyxia, hemorrhage, infections, dehydration, and low blood sugar, and finally—most important of all—intense emotion or psychic trauma. The attending changes in the fluid matrix of the body may become harmful and distressing if the emotional stress is not followed by the appropriate action. The effect of autonomic stimulation is catabolic and brings about liberation of body energy. The parasympathetic division of the autonomic nervous system has an anabolic character, conserving energy during rest and recuperation. Flow of saliva and gastric secretion, heightened motility of the intestines, facilitate digestion and assimilation of food. The heart muscle is afforded rest by the reduced heart rate brought about through vagal stimulation.

The largely antagonistic functions of the two divisions of the autonomic system have formed the basis for dividing individuals into vagotonic and sympathicotonic types. While it is true that the two great systems which integrate the circulatory, respiratory, digestive, and genito-urinary functions are in a state of mutual balance, at times either one special viscus separately or all the viscera simultaneously may be influenced in one direction or the other; for instance, the heart beat may be accelerated as part of emotional excitement, together with sympathetic stimulation of all the other viscera, or the heart may beat rapidly as the result of lessened vagal inhibition without simultaneous change in the activity of the other organs.

Animals which have been totally deprived of sympathetic activity by having had the paravertebral ganglia from the neck to the lower lumbar regions removed become vulnerable to cold, have markedly reduced ability to perform muscular work, and lose the hair-raising power. The peripheral arteries lose their tone only temporarily, heart rate and blood pressure show only slight changes, and there is no tendency towards clear-cut vagotonia. In a protected constant environment the animals are little im-

paired but are markedly hampered in meeting the stress of changing circumstances. They would be in constant danger of disaster unless action were taken to correct the conditions to which the autonomic nervous system adjusts in a purely automatic fashion.

It is important to add observations about the chemical reactions within the autonomic nervous system. It is a fundamental fact that excitation in the autonomic nervous system may be sustained by chemical agents which are produced in the body, namely adrenalin for the sympathetic or adrenergic, and acetylcholine for the parasympathetic or cholinergic. Much information about the autonomic nervous system has been gained by studying the reaction of animals to these substances. Clark (1938) gave a detailed pharmacological description of the effect of these substances in man. The most important adrenergic substances are adrenalin (epinephrine), sympathin, benzedrine; and the most important cholinergic are acetylcholine and pilocarpine. Inhibitors of the sympathetic system are ergotoxin and nicotine. Inhibitors of the parasympathetic are atropine and nicotine.

5. *The Effect of Chemical Agents and Clinical Applications.* The autonomic neurological examinations in the clinic are less developed than are those of the cerebrospinal system. The clinical manifestations of vigorous stimulation of the autonomic system can best be demonstrated by the injection of adrenalin and acetylcholine. Such injections are followed by a characteristic picture. Sympathetic stimulation (or adrenalin injection) results in increased heart rate, heightened blood pressure, dry mouth, elevated blood sugar, increased leucocytosis, tremor of the extended hands, sweating palms, and pallor of the face. Parasympathetic stimulation (or acetylcholine) is followed by sweating of the body except for the hands and feet, salivation, labored breathing, increased heart rate, lowered blood pressure, flushed face, and subjective complaints of feeling hot, light-headed, and dizzy.

It is of interest that the rate of activity during interviews with the clinician is markedly different when the patient has been stimulated or has been given acetylcholine. Injection of the former is followed by an inhibited, uncommunicative stage; after the injection of the latter subjects are liable to speak freely, rapidly, and with little reticence.

Drug therapy of states of autonomic instability has been carried out with both stimulant and depressant substances.

By far the most important of these drugs is adrenalin, which is secreted by the chromaffin cells of the suprarenal gland. These cells are innervated directly by preganglionic neurons as though they were analogous to the ganglion cells of the post-ganglionic neuron. Its active principle is $C_6H_5(OH)_2\cdot CHOH\cdot CH_2\cdot NHCH_3$. It is known as adrenalin to the medical profession and as adrenin to the physiologists when they refer to the actual secretion in the gland. The effects are identical with a widespread discharge in the sympathetic system except that sweat glands are not stimulated. The point at which it produces its effect is even now not exactly known. It obviously does not act directly on the sympathetic nerves because its action persists when these nerves have degenerated. It also does not directly affect the contractile mechanism of smooth muscles (Dale, 1906). Probably some intermediate substance between the nerve endings and the contractile mechanism is involved. Cannon (1937) has described this as the neuro-effector mechanism. When very small amounts of adrenalin are given there may be reversal of the effect. For instance, a moderate amount will produce constriction in the small blood vessels of the skin; a very small amount, however, will bring about vasodilation. This difference is due to the fact that the substance affects not only the vasoconstrictor mechanism but also the vasodilator. The constrictor mechanism is more powerful and has preponderance unless it is paralysed by ergotoxin. Injection of adrenalin after ergotoxin produces vasodilation sufficient to cause a fall in blood pressure.

The word sympathin has been applied by Cannon (1921) to a substance which seems to be produced at the junctions of sympathetic nerves with smooth muscle cells. It has effects much like adrenalin but elevates the blood pressure after ergotoxin. Out of this substance may be separated two fractions, one an excitor, the other inhibitory; their formulae are still unknown.

Closely related to adrenalin chemically are ephedrine, benzedrine (amphetamine sulphate), and mescaline. While ephedrine is largely used for its peripheral effects, causing changes similar to adrenalin but more lasting and effective

even when taken by mouth, benzedrine, in addition to mild peripheral adrenergic effects, shows a marked action on central nervous system functions (Myerson, 1936). It has been used to reduce mood depression and also to counteract the depth of surgical anesthesia and the effect of over-doses of barbiturates (Michelson, 1939).

Ergotoxin (Dale, 1906) paralyses the excitatory action of sympathetic nerves. Like adrenalin it acts on the intermediate substance between the nerve endings and smooth muscle cells. Its power to relax vasoconstrictor tone is used to combat migraine.

Nicotine, the alkaloid of tobacco, stimulates the activity of the sympathetic junctions in the ganglion cells of the autonomic nervous system when given in small amounts but is paralyzing in larger amounts.

Powerful stimulation of the parasympathetic system occurs after the administration of acetylcholine, which in humans often is administered in the form of a more stable substance, acetyl-beta-methyl-choline hydrochloride. It otherwise would be rapidly destroyed in the blood stream by the choline esterase. This destruction can be slowed or prevented by the administration of physostigmine. The effects of acetylcholine are a powerful stimulation of sweat, salivary and tear glands, also of the glands of the bronchial tubes and of the gastro-intestinal tract. There is marked dilation of the blood vessels of the trunk and face and marked increase in motor activity of the intestines. There is also a fall in blood pressure and a constriction of the bronchial tubes.

Atropine inhibits all the effects of acetylcholine and, curiously enough, also paralyses the sweat glands. This became understandable when Dale and Feldberg (1943) demonstrated that the parasympathetic fibers to the sweat glands respond to cholinergic stimulation.

That nerve impulses themselves might be mediated in a chemical fashion was first suggested by Elliott (1935). Otto Loewi (1921) showed that fluid used to perfuse the heart of a frog during stimulation of the vagus nerve contained a substance which slowed the heart of a second frog. The same sort of substance then was shown to occur in the salivary glands after stimulation of the chorda tympani nerve and at the ganglionic synapses (Feldberg and Gaddum, 1934), even including the endings of the

splanchnic fibers which supply the adrenalin-secreting cells in the adrenal medulla. At the end of postganglionic fibers Cannon discovered the production of the adrenergic substance sympathin, mentioned above. The unique function of these chemical substances, in addition to the mediation of nerve impulses, seems to be to distribute autonomic impulses through direct stimulation of smooth muscles, only one per cent of which have separate nerve endings (Stoehr, 1928). It seems that the locally produced sympathin, the circulating sympathin, and the circulating adrenalin all work together to unify and synchronize the operation of the sympathetic system. It now appears probable that quite generally a chemical step intervenes between the electric impulse which is transmitted through a nerve fiber to its ending and the effector mechanism in muscles and glands. In the sympathetic system and in the nerves supplying the skeleto-musculature the reaction is mediated by an acetylcholine-like substance which is destroyed within a minute fraction of a second and produces only a very localized response. Sympathin and adrenalin show a more widespread and sustained effect.

An important observation is the *sensitization* phenomenon. Even after an organ has been deprived of its sympathetic fibers it will still be stimulated by these circulating substances. Curiously enough, when an organ is deprived of its sympathetic nerve supply, its sensitiveness to circulating adrenergic substances is greatly increased. As a result, the injection of adrenalin produces an increased constriction of peripheral blood vessels after the destruction of the autonomic nerve supply. The sensitization phenomenon seems to account for the fact that there is no chronic flaccid paralysis of smooth muscles after denervation. There is little functional impairment because the muscles respond vigorously to the circulating substance in the blood. Cannon (1938) has formulated this as follows: "When in a series of efferent neurons one unit is destroyed an increasing irritability to chemical agents develops in the isolated structures. The effect is maximal in the part denervated." This phenomenon has become of major importance in surgical efforts to relieve spastic conditions in the arteries of the extremities (Reynaud's disease) by removal of the sympathetic nerve supply. Early operations failed because after cutting the postganglionic fibers

the arteries, being sensitized, became more spastic than before. This sensitization does not occur after interruption of pre-ganglionic fibers. Surgical interruption of these fibers, therefore, relieved the spasticity.

The *hypothalamus*, situated in the diencephalon at the floor of the third ventricle just above the optic chiasm and the sella turcica (the latter containing the hypophysis), is the principal center for integration of visceral functions controlled by the autonomic nervous system. The constituent cell masses may be divided into four groups, an anterior portion, a middle portion, a lateral area, and the posterior. They have elaborate connections, both afferent and efferent, with the thalamus and with the cerebral cortex. Stimulation in the laboratory of the anterior and medial portions can be shown to produce sweating, contraction of the bladder, inhibition of the heart, and increased motor activity of the stomach and the intestines, largely a parasympathetic picture. Stimulation of the posterior and lateral nuclei, on the contrary, gives a picture of sympathetic stimulation, producing acceleration of the heart rate, elevation of blood pressure, inhibition of the intestines, and dilation of the pupils. While this topical relationship to the major divisions of the peripheral autonomic system is important, the most significant regulatory functions have to do with the maintenance of proper metabolic functions. Destructive lesions in the laboratory or by disease (brain tumors) indicate that cell destruction in the posterior part will be followed by a fall in basal metabolic rate, heart rate, and temperature. There is also a general state of lethargy and sleepiness. Destruction in the middle portion may be followed by high blood sugar, violent gastrointestinal activity, ulcerations of the intestines, and disturbed heat regulation. Destruction in the frontal aspect causes a marked disturbance in water metabolism (diabetes insipidus). It is followed by degeneration of the hypothalamic parasympathetic outflow and degeneration of the posterior lobe of the pituitary gland.

On the level of behavior, any of these syndromes are likely to be accompanied by changes in personality, varying from depressed to excited states. In animals Fulton and Ingraham (1929) found that lesions of the anterior hypothalamus tend to produce excited states while posterior lesions are likely to be accompanied

by lethargy, indifference, depression, and a tendency toward catatonia (Harrison, 1940).

The hypothalamus is also an important integrating center of emotional responses. Perception, memory, or anticipation of disturbing situations or perturbing individuals find access here to effector systems involving skeletal-muscular activity—fight, flight, pursuit, sexual activity or expressions of grief. Disturbances in the appropriate execution or untimely occurrence of these response patterns are the chief interest of psychiatry in autonomic neurology.

In anxiety neurosis the visceral part of emotional expression occurs, often without reference to any specific disturbing situation, is not recognized as emotion by the patient, and is considered as illness in a specific organ; for instance, heart acceleration to the patient heralds heart disease. Autonomic neurology makes the psychiatrist seek for evidence of other disturbed visceral functions. He will identify the patient as a "multiple complainer" who, in addition to heart disturbance, shows other evidence of autonomic imbalance. Attacks of such imbalance may occur in rather pure syndromes, either of an cholinergic or of an adrenergic type; there may be a combination of dry mouth, pupillary dilation, heightened blood pressure, accelerated heart beat, pallor, and intestinal sluggishness, or there may be a combination of flushed face, hot flashes, lowered blood pressure with lightheadedness, increased intestinal activity, sweating, and salivation. In the majority of instances, however, one finds evidence of mixed autonomic disturbance. Both the adrenergic and cholinergic types of anxiety attacks may be reproduced by injections of the appropriate substances (Lindemann and Finesinger). The clinical work may be directed either toward reducing the irritability of the autonomic nervous system by sedation, or toward shifting the balance of the autonomic nervous system by the administration of appropriate sympathomimetic or parasympathomimetic substances, or one may try to produce adequate expression of the whole emotional response pattern involved by recalling with the patient the original situation which set up the abnormal emotional response (psychotherapy).

Regional autonomic disturbances comprise the clinical syndromes which are grouped together as psychosomatic disorders. Migraine, due to spasms of cranial arteries, may be re-

lieved by ergotoxin; bronchial asthma, due to spasm of the bronchial tubes sensitized to parasympathetic stimulation, may be alleviated by adrenalin; spasms of the arteries in the extremities may be alleviated by removing their sympathetic supply; chronic high blood pressure (essential hypertension) has been successfully treated by removing the sympathetic supply of the large arteries. Gastric ulcer, spastic and ulcerative colitis have usually required a careful review of sources of emotional disturbance in addition to medical or surgical management. Advances have recently been made, however, in controlling autonomic stimulation of the involved organs. Interruption of the parasympathetic supply of the stomach has been tried to prevent further ulceration in the presence of peptic ulcer.

Autonomic neurology is, then, the study of the integration of visceral functions, the maintenance of homeostasis, and the adjustment of the organism to disturbances of emotional reactions.

ERICH LINDEMANN,
Harvard Medical School

ASPECTS OF BLINDNESS, PSYCHOLOGICAL.—The term "blindness" in common usage includes not only total absence of vision but all degrees of visual defect so severe as to prevent one from carrying on the ordinary activities of life for which sight is essential. The following definition of blindness in ophthalmological terms is the one most widely accepted: "Central visual acuity of 20/200 or less in the better eye with correcting glasses; or central visual acuity of more than 20/200 if there is a field defect in which the peripheral field has contracted to such an extent that the widest diameter of visual field subtends an angular distance no greater than 20 degrees." In Warren's *Dictionary of Psychology* blindness is defined as "A generic term denoting inability to see, whether the cause of the abnormality be peripheral, central, or intermediate."

Neither of these definitions takes into consideration the factor of age at onset of blindness, which is of great importance from a psychological point of view, since a person who becomes blind later in life is able to make use of his visual memory. It is generally agreed that blindness occurring before five years of age deprives the individual gradually of useful

visual memory, although no experimental study has been conducted to support this assumption.

Any discussion of the psychological effects of blindness must take into consideration (a) degree of sight and (b) age at onset of blindness. The full extent of the restrictions resulting from the visual handicap may be felt only by individuals who have been totally blind from birth or who became blind at such an early age that they have no workable visual imagery. The amount of sight and the age at onset of blindness, however, are not the only factors that cause differences in the extent to which the handicap affects the individual. Intelligence, environment, education, and, probably, inclination to certain psychological types of imagery and learning are some of the other factors which determine the usefulness of vision in each individual case.

Blindness restricts the individual in three basic ways:

(1) *Restriction in the range and variety of concepts.* Totally blind individuals must build up their conception of the world by the use of the remaining senses. In doing this they must rely almost exclusively upon tactual and auditory perceptions and kinesthetic experiences. Although hearing gives certain clues in regard to distance and direction it does not convey any concrete idea of objects as such. Perception of space (space broadly interpreted as including everything extending into three dimensions involving form, size, position, distance, and direction) can be achieved by touch, in which kinesthetic sensations play a more or less important role. Tactual perception, however, has distinct limitations because of its inherent necessity for direct contact with the object to be observed. Certain objects are inaccessible for direct contact, as for instance the sun, or clouds; other objects are so large that they cannot be tactually observed in toto, as mountains or lakes; others are so small, tender, or fragile that they cannot be touched, e.g., some animals or flowers. Objects in motion, live objects, and objects under certain conditions, such as burning or cooking, do not lend themselves to observation by touch partly because they change their shapes and positions and partly because of the danger involved in direct contact. It must also be recognized that the sense of sight permits much more perceptual activity than the sense of touch be-

cause the eyes are almost constantly open to stimulation from the outer world while touch needs to be actively applied for the purpose of securing impressions.

Unlike space perception, color perception, which results from stimulation of the retina, is solely a visual function. Therefore, totally blind persons cannot perceive color at all, although they acquire substitutive ideas for colors through sensory, verbal, or emotional associations. The idea of the color *blue*, for example, might be determined by the association "blue sky." Thus all or some of the different sensations and emotions caused by fine weather may build up substitutive ideas of the color *blue*. These ideas not only have value subjectively as components of the blind individual's world of imagery but also enable him to communicate with the seeing in common terms, though not on the basis of common experiences.

These limitations in the perceptual field cannot but result in a restriction in the range and variety of the ideas and concepts of blind individuals.

(2) *Restriction in the ability to get about.* This restriction implies a twofold handicap in that it limits the blind person in his locomotion and also makes him dependent upon the assistance of others, thus affecting his social relationships and attitudes in varying ways and degrees. A blind person cannot get about by himself nearly so much as a seeing person can in order to change his surroundings and secure opportunities for observation and activity. Therefore, besides being limited in the perceptual field, blind individuals from infancy on are exposed to a reduced number and variety of experiences. The restriction in the ability to get about must be recognized as exerting great influence on the over-all development of the blind child. He needs to be supplied with experiences and opportunities for activity which most other children meet in the ordinary course of their development.

When the individual grows out of the comparatively sheltered life of the home or the institution and is confronted with the task of social and economic adjustment to the world of the seeing this restriction carries new implications. In the extreme case, the blind individual not only may take help in getting about for granted but may expect to be helped along all

lines. He has fallen back to a level of protection which is characteristic of infancy and will develop beyond it only if his self-confidence is built up and if he accepts his handicap in its real proportions. On the other hand, a blind person may resent and even revolt against being aided in many of the activities which he knows seeing persons can pursue independently of others. Either of these attitudes—if it persists as a disturbing influence—indicates a lack of adjustment and has its deeper cause in the non-acceptance of the handicap. Although the reactions of the majority of blind individuals do not follow these extreme patterns, restrictions in the ability to get about are unquestionably cause for feelings of deprivation and frustration.

(3) *Restriction in the control of the environment.* Among the human senses sight is the one sense which overcomes distance and gives at the same time details and relationships of form, size, and position. This "object quality" of visual experiences permits a contact with and a control of the environment far greater than that achieved by all the other senses. Lack of sight causes detachment from the physical, and to a less degree from the social, world. A blind person, for instance, cannot become informed about his situation within the environment by any rapid process as seeing persons can by just glancing around. The clues which he might get through hearing and through touch observations within his reach give him only very little that could assist him in controlling his environment and himself in relation to it. This detachment affects the blind individual in different ways during his development. The blind infant, for instance, does not reach out or crawl towards objects, as a seeing child does, because nothing entices him to do so, unless he is made aware of these objects by other sensory impressions. Actions of daily life, such as eating a meal, which are simple for the seeing, assume different proportions when they are not controlled by sight. Also, the blind individual from infancy on cannot acquire behavior patterns on the basis of visual imitation. In social situations he cannot become informed about the required behavior as seeing people can simply by watching others. This makes conforming with the group from childhood on a much more difficult task. The isolating effect of

this detachment restricts the blind individual in his control of the environment and results in increased feelings of insecurity and in a state of higher nervous tension.

The question as to how the three basic restrictions discussed affect the lives of blind individuals can at the present be answered only in a rather general way because we are lacking in scientific studies which would enable us to make any statements on the basis of actual case research. It can be said, however, that the basic limitations radiate into the personal, social, and economic spheres of the individual's life and, since these spheres vary in depth, extension, and development from individual to individual, the limitations caused by blindness have a different effect in each case.

In dealing with the effects of blindness on the perceptual level we must recognize that the experiences of the blind, although different from those of the seeing, have the same subjective value for them and contribute to just as complete and satisfactory an individual conception of the world as that of other persons.

The perceptual restrictions, however, give rise to verbalism and may cause certain behavior forms known as "blindisms." Verbalism is caused by the comparative paucity of first-hand experiences which frequently forces blind children to use mere words without an understanding of their real meaning. A certain amount of verbalism is unavoidable and socially necessary but educational methods should be directed towards concrete experiences in order to give real meaning to as many words as possible. Blindisms are a result of lack of stimulation from the external world which furthers the child's concentration on the self and encourages the exercise of self-stimulation. Blind children resort to such activities as shaking the head rapidly, or swaying the body back and forth. These blindisms usually disappear in the course of a child's development if sufficient stimulation is provided.

The effects of blindness also tend to drive the blind individual into a world of unreality and phantasy in which he may find compensation for his real or supposed failures. This may be the case particularly when the individual meets with difficulties in his social adjustment, such as rejection by parents, playmates, or a prospective employer.

Psychological problems of blindness received consideration in the early period of scientific psychology. William James as well as Wilhelm Wundt discuss in their standard works the problem of spatial perception by the blind. The first systematic study dealing with psychological problems of blindness as such dates back to the experimental laboratory of Wundt where Theodor Heller conducted investigations which he reported in his *Studien zur Blindenpsychologie* (1895). Since then, psychological research in the field of the blind has dealt mainly with problems of sensory experiences of the blind as compared with those of the seeing, with the ability to perceive obstacles, and with the measurement of intelligence. Only recently—and mainly as an outcome of social-work efforts—has the study of personality problems of the blind received attention.

Numerous discrimination experiments have been carried out with blind subjects proving that in general they have no greater sensory acuity than other individuals. These experiments tested discrimination of pressures and of weights, sensitivity to temperature changes, ability to localize sounds, etc. The superior achievement in the practical use of the remaining senses that blind persons may show is the result of attention and increased use. Experiments on the memory of blind children—rote memory, recall, and logical memory—also do not reveal any superiority in the blind. All these investigations have contributed to disprove any assumption of innate or automatic "sensory compensation."

There are two problems in the field of sensory perception of the blind which have been widely investigated: the tactual perception of space and the ability to perceive obstacles. Theories disputing the possibility of acquiring a conception of space by touch have been set forth as well as theories analyzing the different ways in which blind individuals acquire tactual knowledge of space and of spatial qualities of objects. There is now a general consensus of opinion that the tactual space of the blind is different from the visual space of the seeing. Two types of tactual perception by the hands have been differentiated for the purpose of psychological analysis. Enveloping touch, by which small objects are enfolded with one hand or with both hands, is called "synthetic" because

the object is perceived as a whole simultaneously. The second type of tactual perception is applied to larger objects which extend beyond the limited embrace of one or both of the hands. In this the moving hands follow the shape of the object and, if it is large, the arms and the whole body may actively participate. This kind of touch perception is called "analytic" because it gives successive impressions of parts of the objects. The question of how these successive perceptions lead to a unified idea of the object as a whole has not yet been conclusively answered. Mental processes of tactual space contraction and tactual space expansion and the formation of spatial "Gestalten" are given as explanations by various theories. The importance of sensations of movement in the tactual perception of space is stressed by all investigators of this problem.

In the task of orienting himself and finding his way in familiar or in unfamiliar surroundings the blind person makes use of practically all his senses: his sense of hearing is constantly active in observing all kinds of sounds, including echoes; he interprets odors which come from many sources; he notices changes of temperature and air currents; his feet feel the nature of the ground; he observes distances in terms of time, through movement, and through sound—in fact any clue that he can obtain is interpreted for the purpose of orientation.

The perception and avoidance of obstacles by the blind is a long-standing topic of speculation and research. Some investigators have explained this "obstacle sense" as depending upon auditory, temperature, or pressure sensations, or upon a combination of these, usually with the supposition that increased sensitivity in one or more of these sensory fields is a basic factor. Others have suggested much more complicated explanations. It was found that not all blind persons possess the ability to perceive obstacles and that many sighted persons either have it or may acquire it by practice. Auditory stimulation has been claimed most consistently as being necessary for the perception of obstacles. The results of the latest investigations refute the pressure theory, insofar as it applies to the face and other exposed areas of the skin, and prove that aural stimulation (either heard or felt) is both a necessary and a sufficient condition for the perception of obstacles. Sound waves of

higher frequencies are assumed to play an important role in it.

The use of intelligence tests with blind children has received considerable attention. The first adaptation for the blind of the Binet-Simon Scale was made by Robert B. Irwin and H. H. Goddard, in 1914. Since then, Samuel P. Hayes has developed several adaptations of the Binet-Simon test, particularly the Hayes-Binet scale of 1930 based on Terman's Stanford Revision and the Interim Hayes-Binet Intelligence Tests for the Blind, 1942, based on the 1937 Terman-Merrill Revision. The verbal series of the Wechsler-Bellevue Intelligence Tests, with the vocabulary test substituted for the digits test, is also used in testing the blind. Of the group intelligence tests, the Kuhlmann-Anderson tests have been adapted for use with blind pupils.

According to Hayes the percentage of blind pupils in the average and superior intelligence brackets is smaller than that of the general school population in these brackets and the percentage of dull, border-line, and feeble-minded is much larger. There are no studies available on the intelligence of blind pre-school children or blind adults. It must be understood that the instruments used for measuring the intelligence of blind children are those devised for seeing children and adapted for the blind by omitting certain items that cannot be used with the blind and by substituting others.

The use of achievement tests with blind pupils reveals that although blind children begin their schoolwork more or less on a par with the seeing they fall increasingly behind as they progress from grade to grade. Since schools for the blind follow the grade standards generally accepted in public schools the retardation of blind children manifests itself in an increasing overage of the pupils. Besides blindness as such—which affects particularly the information component of the tests—heredity, poor environment, illness, emotional conflicts, and late admission to school are some of the factors which contribute to the unfavorable distribution of IQ's and to the educational retardation.

Another contributing factor is the slowness of braille reading, which limits blind children in the amount of material they can read. This

is of particular disadvantage since blind children must rely upon reading as a source of knowledge to a much greater extent than do seeing children. Braille is the most important reading medium for the blind. It is a touch system in which the letters of the alphabet are represented by various combinations of embossed dots in cells two dots wide by three dots high. Although contracted systems of braille are used, braille reading is slow as compared with visual reading, oral or silent. Blind children read in braille only one-third or one-fourth as fast as other children do in silent visual reading. (In general three times as much time is allowed for the completion of tests involving braille reading.)

Experimental work in the psychology of touch reading was done mainly by Karl Bürklen prior to 1917. It showed that the legibility of braille characters does not depend upon the number of dots but upon their configuration; that reading is fastest when both hands are used; that the index fingers seem superior to the others; that good readers employ touch movements in a straight running line with slight and uniform pressure, while poor readers employ irregular touch movements and exert heavier and more irregular pressure; that there is very little decrease in touch sensitivity even after long reading; and that braille reading cannot be considered as especially fatiguing. Further research on braille reading which would take into consideration the present findings in the field of visual reading is greatly needed.

The study of personality characteristics of the blind is only in its beginning. In the available literature it is stressed that the handicap does not affect all personalities in the same way; that the reactions of the social environment to the handicapped person are of basic importance and that it is not so much the handicap as the social treatment which causes emotional conflicts and feelings of inferiority and insecurity in the blind individual. Blind adolescents were found to be below the norms for the seeing in respect to personal and social adjustment.

Many blind persons have written about their own experiences; some of them very subjectively but some with considerable candor and objectivity. Two extreme attitudes toward blind-

ness are represented in these writings. The loss of sight is regarded on the one hand as nothing but "the loss of a convenience" and on the other as a handicap that "changes and utterly reorganizes the mental life of the individual." These personal documents—indicative as they may be—must largely be classified as "literature of opinion." Scientific studies of the personal and social effects of blindness are needed to make up a body of "literature of fact" in this field.

CHILD PSYCHOLOGY.—In so far as the sensations, feelings, and behavioral capacities of children overlap those of adults, child psychology parallels general psychology, with the same divisions of subject matter. Nevertheless, a distinctive approach becomes possible from the fact that childhood is the period of rapid growth and development. Hence, child psychology may be conceived as the science of mental and behavioral development and of the factors which affect it and modify it. The great value of child psychology lies in its potential application to education, child welfare, and preventive mental hygiene. Accumulation and verification of knowledge must, however, precede its application. In the past, zeal for quick results often led to hasty generalization. Rules for child training were often laid down dogmatically and copied from one manual to another, with no attempt to observe objectively the results of applying the rule or the results of omitting its application. Careful observation and experimental controls were taken for granted in adult psychology at a time when child psychology was still in the stage of authoritarian dogma. During the past fifty years, however, methods of child study have become increasingly precise, and a reliable body of information is accumulating.

Methods. The earliest attempts to present facts in child psychology were biographical records of the authors' own children. The kindergarten movement provided large groups in which several children could be observed under identical conditions, and many of the most interesting studies have been made in connection with kindergartens and nursery schools.

The parent with a pride in his child, the teacher eager to prove her own methods successful, and the philosopher seeking support for his theory are all open to the suspicion of prejudice in their observations. The safeguard of objectivity is to have several disinterested observers; but to have the children surrounded

by a gallery of observers would immediately alter the situation. Children behave quite differently if they are conscious of an audience. The Yale Clinic of Child Development has solved the problem by two simple devices: (1) the one-way screen behind which a score of observers may watch the spontaneous behavior of children who do not know that they are being watched; and (2) the motion-picture camera to record the activity of children who do not know that they are being photographed. On the motion-picture screen it is possible to flash in rapid succession the records of the same child taken months or even years apart. With such data, it is possible to show how the same child's response to the same stimulus alters as his growth progresses. Thousands of questions about the genesis and the control of behavior will probably be answered by extensions of this method.

Unfortunately, the thoughts, feelings, and motives of children must still remain matters of conjecture as we watch their performance on the screen. This fact is explicitly recognized by the psychologists who employ these objective records. Meanwhile, other psychologists have sought other methods for investigating the thoughts, feelings, and motives of children.

Many data on the inner life of children have been collected by the questionnaire method, first introduced by the Berlin Pedagogical Society in 1869 and subsequently popularized in America by Granville Stanley Hall. The method is open to at least two sources of error: (1) different children may interpret the same question diversely; and (2) some questions may be answered untruthfully, especially if the true answer be incompatible with self-esteem or with the child's notions of what the adult questioner expects.

An indirect approach to the study of emotions and motivation is made possible by the so-called projective techniques. In these indirect approaches, the child unwittingly reveals many hidden personality factors while ostensibly let-

ing his imagination play with the test materials (toys, ink-blots, pictures, unfinished stories, and the like). These techniques, however, have been criticized on the ground that they are not sufficiently objective, and that the actual data supplied by the child are very meager compared with the interpretations read into them by enthusiasts for these methods.

Clinical data, also, though often they are the only evidence we have for questions of great import, fall short of the objectivity and the reliability that must remain our ideal as scientists. The child is usually brought into the clinic because of some behavior problem. He is sensitive, emotionally wrought up, and fearful of revealing anything that may count against him. Likewise, parents and other persons who have had any responsibility for his training are usually on their guard lest they reveal anything that may reflect upon their own adequacy. In some states, clinical data are collected and subjected to statistical analysis on a state-wide basis. A report of this type is a valuable contribution to science, provided that these data are recognized for what they are—namely, summaries of statements collected from individuals of various degrees of veracity, many of them having been made under embarrassing circumstances. We need to remember that no amount of statistical manipulation of data can introduce any more truth into the data than there was to begin with.

Furthermore, a clinician's skepticism as to the client's veracity does not increase the reliability of the data. In fact, the reverse is true. The moment he begins the work of editing his client's statements—attributing this one to "wishful thinking," that one to "rationalization," and so on—his own preconceived theories have crept into the situation. Thus, the case history is no longer a history but a historical novel, with the interpreting clinician as the novelist.

Mental testing and other so-called measurement procedures yield more reliable data than the questionnaire and the clinical interview. The early testers emphasized cross-sectional studies of large numbers of children at specified age levels. Recent emphasis has been upon longitudinal studies, in which the same children are tested and observed at regular intervals over a period of years.

Repeated tests give psychologists and edu-

cators an effective tool for measuring the results of any educative procedure, provided that matched groups are used to rule out the effects of extraneous factors. The control group should be initially equal to the experimental group and exposed to all the same environmental influences except the one being tested. Ideally, each member of the experimental group is matched with a member of the control group in chronological age, mental age, physical development, socio-economic status, and every other factor that can be conceived to have any possible bearing upon the problem.

It is, of course, easier to postulate such equality as a desideratum than to attain it in actuality. No matter how many specific measurements we may make, some factor is likely to be overlooked, and any differences that we find between the experimental group and the control group at the end of the experiment may be due to this forgotten factor. The hardest factor to equate is that of heredity. No two children, not even siblings, can be assumed to have the same heredity except identical twins. Hence, the ideal control group is that which is composed of the identical twins of the experimental group. Gesell, McGraw, and others have used the method of co-twin control in some of their most important experiments. Newmann, by collecting histories of pairs of identical twins separated in early childhood, has learned much about the relative importance of heredity and environment. He has found that heredity contributes the most to physical development and the least to character, with intelligence occupying a middle position.

All the earlier studies focused attention upon the child's behavior or his putative emotions. Situational analysis has been emphasized in some recent studies; and there have been observational studies of mothers, teachers, and even dentists, as social stimulators of the child. It has been found that domineering behavior often arouses rebellion; so does protective behavior that thwarts the child's growing desire for independence. Parallel check lists enable the observers to record the child's exact response to a particular item of adult behavior before it is forgotten or overlooked in the welter of subsequent incidents.

Important results of childhood conditioning may not appear until later life. Longitudinal

studies are complicated by the fact that the children are exposed to a multitude of conditioning factors beyond the control of the investigator. For this reason, animal experimentation is sometimes used to provide an experimental check upon theories not otherwise accessible to experimentation. Though results upon animals should not be accepted uncritically as applying to human beings, they do often provide a valuable supplement to other data, especially when the animal experiment was designed to test a theory originally growing out of clinical experience with human beings.

Explanatory Principles. Laymen and beginning students desire simple explanations. They want to be told briefly and at once the cause of stuttering, or of reading disability, or of delinquency. Now, actually each of these conditions is very complex. Each may result from a number of causes operating successively or simultaneously. Insistence upon a single cause for every phenomenon is responsible for many fruitless controversies: for example, the controversy over heredity versus environment. Actually, both heredity and environment contribute to every act that the child performs. At any given moment the individual is the product of all his heredity plus every environmental influence that has played upon him during his entire previous life.

Modern psychology views the child as a unitary psycho-biological organism, responding to environmental stimuli in so far as these appear relevant to his needs and continually modifying his behavior as maturation and learning proceed.

Learning is the acquisition of behavior patterns, ideas, and attitudes as a result of experience. It is contrasted with maturation, which is the development, both structural and behavioral, resulting from the growth of the organism. Thus, maturation includes all those changes that result from the hereditary potentialities. Learning includes all those behavioral changes (desirable and undesirable) that result directly from adaptations to environmental stimulation. It excludes those changes in behavior which result indirectly from alterations in body metabolism due to malnutrition, limited water intake, bad air, and the like, except in so far as these conditions stimulate the organism itself to active behavior.

Much future research should be devoted to the neural and the behavioral effects of biochemical conditions resulting from such conditions as faulty nutrition, polluted air, and so on. Though the facts are yet to be ascertained, it is entirely possible that these conditions may be partly responsible for the fact that underprivileged children are, on the average, less efficient scholastically than the children of the privileged.

Nevertheless, the child is, almost from the start, a social organism as well as a biological one. His needs include love, acceptance, and approval. Even at the age of eight weeks, infants notice people more than things; and by the time a child is forty weeks of age, he seems to make a definite effort to please and also to imitate. From then on, throughout the preschool period, he becomes increasingly responsive to suggestions, unless these suggestions run strongly counter to his biological needs, his present sets, or his previous learnings. This generalization is not contradicted by the fact that many children go through a period of negativism around the age of two or three years. To the neutral observer, this negativism is just as much a response to suggestion as any of the child's other responses. The socially suggestible child imitates a bad example as readily as a good one. The stimulus to negativism on the child's part is domineering activity on the part of an adult. H. H. Anderson has shown that domination by the adult leads either to apathy or to rebellion on the child's part, whereas *integrative behavior* leads to cooperation and desirable learnings. It is upon this social responsiveness of the child that practically all education and training depend.

Educational Premises. The imparting of knowledge and skills is only part of the educator's task. The child's emotional attitudes toward himself and his social group are even more important. We cannot educate his "mind" without at the same time affecting every other aspect of his personality. It is therefore advisable to have in mind not only specific goals in subject matter but also the broad goal of education as a whole. What sort of person do we want this child to become? Do our present educational impacts help or hinder the acquisition of this desired personality?

Every educational program must be based

upon some idea of the original nature of the child, his present status, the goal to be sought in educating him, the degree to which this goal is attainable, the extent to which its ultimate attainment must depend upon natural growth on the one hand and educational intervention on the other, and finally the safest, most efficient, and most economical means of reaching the goal.

The goal of the modern educator is the poised, self-confident, healthy, happy, socially contributing adult. It is now recognized that this type of adult is most likely to result if poise, self-confidence, health, happiness, and social contributions are made possible throughout childhood. Self-confidence is built upon experiences of success. Health is safeguarded by providing adequate and sufficiently varied food, opportunities for restful, undisturbed sleep, constructive guidance in health habits, and above all, protection from injury, infection, and especially from the disturbing emotional experiences which are now known to cause a high percentage of health problems. Happiness is a by-product of health, satisfied needs, unimpeded growth, successful efforts, and harmonious social relationships. Poise is the absence of emotional outbursts and the ability to remain calm even under trying conditions. It develops gradually as the individual learns to cope successfully with the problems that confront him.

Social contributions become increasingly *possible* as the child gains in knowledge and skill. Whether he will *wish* to make such contributions depends largely upon his previous experiences. The preschool child is usually eager to help. When older children dislike work, this is the result of adverse conditionings. In some cases, the child has been ridiculed for mistakes or scolded for accidents. In others, he has been led to expect rewards that were not forthcoming. In other instances, work has been assigned as a punishment, and hence attitudes toward punishment have been extended to work by association. In still other instances, the program of work assigned to the child has been so excessive or so ill-timed as to interfere with normal play interests or to create a humiliating contrast between this child and his associates. On the other hand, if a child's earliest efforts to help out with the necessary work of the household are rewarded with success, appreci-

ation, and appropriate recognition, the habit of contributing actively to the general welfare can be built up as naturally and easily as any of the simple health routines.

The greatest barrier to health and happiness in childhood and to the development of a poised, self-confident, socially contributing personality is the persistence of educational practices which were logical outgrowths of mistaken ideas of child nature formulated before the scientific study of children was begun. The old ideas have long since been abandoned, but practices built upon them are continued with stubborn atavistic persistence.

Throughout the eighteenth and much of the nineteenth century, ideas about children were colored by theological dogmas. The child was thought to inherit an almost demoniacal will along with his original sin. Theologians believed it the first duty of the educator to break the child's will. Modern psychologists recognize no such will. They regard the activities, impulses, and desires of children as natural outcomes of their biological needs and social conditionings. Hence, the problem of the modern educator is to satisfy bodily needs and regulate social conditionings in such a way that desirable behavior results.

Because theologians of earlier centuries believed the child's own impulses were inherently evil and that the parent through long moral training had learned what was best, it was logical that they should insist on absolute obedience. The steady advance of research, however, has shown the extent of our past ignorance. This ought to make us humble and a little skeptical about our dogmatic certainties concerning what is best for the child. But without adult omniscience, the logical excuse for arbitrary authoritarianism is gone. Since neither party knows the whole truth about anything, it is more reasonable for children and adults to grow up together, each respecting the feelings of the other, each making concessions, neither imposing his own will all the time.

As we have said, the first educational goal of the eighteenth and nineteenth centuries was perfect obedience, blind submissiveness to authority as embodied in parent or teacher. Strangely enough, many of the most intelligent men trained under this regime became the rebels and revolutionaries of their time. Mod-

ern psychology offers a simple explanation for this seeming paradox. Overemphasis upon obedience inevitably leads to conflict between parent and child with much frustration (q.v.) for both. The frustrated parent commonly punishes the child, thereby increasing the child's frustration. The child usually enjoys some revenge in the form of stubbornness and misbehavior, but fear prevents him from fully working off the aggressive impulses aroused. They tend to crystallize into repressed hatred. His problem is complicated by the fact that he also loves his parents. He cannot bear to acknowledge the hatred even to himself. It remains an unconscious (or at least un verbalized) attitude, ready to be transferred to any other authorities who try to control him. When he comes to school, he is set to rebel against the teacher and the principal. A little later in life, it is the police who symbolize the hated authority. There is much clinical evidence to show that delinquents come more often from harsh homes than from indulgent ones.

John Dewey and his colleagues of Columbia were among the first to stress the importance of education for democracy by giving the schoolchild early opportunities for democratic participation. Lewin, Lippitt, and others have made observational studies of the functioning of autocratic, democratic, and laissez-faire regimes in boys' clubs, and found the democratic to be the most desirable from every standpoint. Certain cautions need to be observed in introducing democracy to children accustomed to an authoritarian regime. First, the new powers should be introduced gradually. It is best for children to have much experience in making choices for *themselves* before they attempt to legislate for a group. Otherwise their first attempts at democratic government may take the form of passing arbitrary rules (such as those formerly laid down by their elders) and prescribing penalties for the breaking of these rules. Children with sadistic tendencies, and this includes nearly all children who have been repressed or punished very much, sometimes work off their sadistic impulses with social approval under the guise of punishing violations of rules passed by a juvenile democracy. True democracy is a matter of spirit rather than organization. G. Lewin and K. Lewin contend that democratic education cannot start with an

autocratic treatment of the baby and then shift slowly to democratic methods. It should create a democratic atmosphere for and within the actual world of the child.

"Training" versus "Guidance." Older psychologists conceived of the behavioral learning of children largely in terms of "habit formation." Habits were supposed to be definite responses to definite stimuli, becoming increasingly automatic and invariable as a higher degree of learning was achieved. Gesell and his co-workers have shown that this conception of habit is not adequate to the fluctuating behavior patterns of infancy and early childhood. The main stimulus to early activity seems to come from within. The child exercises the neuromuscular mechanisms that are developing within him. Any convenient object in the environment is appropriated for this purpose. At one period, the baby mouths anything he can get his hands on. Somewhat later he will pound with anything. The same wooden block at different periods in the child's life may become (1) something to grasp, (2) something to mouth, (3) something to pound with, (4) something to drop, (5) something to pile up, (6) something to throw, (7) something to build with, and even (8) something to personify, if no doll is available at the moment. Even in the same developmental period, the same stimulus object will elicit quite different responses, depending on the state of the organism. To a hungry boy, an apple is something to eat; but to the same boy after a big dinner, an apple is something to throw. From infancy to old age, behavior seems to depend more on the state of the organism and its consequent needs than upon the exact physical nature of the external stimulus.

Until quite recently it was supposed that the educator ought to decide upon a definite set of habits in conformity with conventions and start inculcating these in the child as early as possible. Each lapse from the prescribed habit was supposed to weaken the habit and make subsequent lapses more likely to occur. Hence, spontaneous, exploratory behavior on the part of the child was regarded as dangerous. Only slowly have psychologists outgrown this point of view.

If social customs were everywhere the same and unalterable, there might be some economy

in a rigid and invariable set of habits; but in a world where folkways differ from place to place and from one social group to another in the same place, and where progress is constantly introducing innovations, rigid, unalterable habits are detrimental to the individual. We should encourage exploratory behavior, and inculcate routines only to the extent that they seem to provide security for the child and peace for the family.

The older concept of "training" presupposed that the trainer should do all the planning, make all the decisions, and push his plans through, by strategy, if not by violence. The modern concept of guidance assumes that the parent will wait patiently for the child's maturing potentialities to reveal themselves, and will then offer as much constructive help as the child seems ready to accept. This does not mean a policy of *laissez-faire*. Children, especially during the preschool period, are very dependent upon adult interest and approval. Where these are lacking, development may be delayed or warped. The child's language, his table manners, his cleanliness, and a multitude of other factors that affect his social acceptance and consequently his happiness, can only be learned under somebody's guidance, usually his mother's. A large part of what is commonly called "manners" consists of specific motor skills, such as the proper handling of cup, spoon, and fork. The toddler is eager to do these things and to do them right. Let him try, even though he spills. Give encouragement for successes. Give simple, intelligible suggestions for improvement. Avoid criticism which humiliates and destroys the incentive to try. Be patient, calm, and casual about accidents. Precision comes through successful practice, leading to self-confidence and ease.

Guidance should be positive and constructive. Instead of waiting till the child does something wrong, and then scolding him, we should direct his attention to desirable forms of behavior. In "Helping Children Learn" (Cornell University Press), Waring and Johnson offer the following suggestions for early guidance practices: notice the first signs of child effort, no matter how small they may be, and make the undertaking achievable, meaningful, and satisfying to the child (1) by physical aid if he needs it, (2) by verbal direction if he does not

yet know what to do, and by specific approval, so that he may know just what behavior is desirable.

Sometimes the most difficult part for the mother is to realize just how much help is needed, and even more important, what kinds of help are *not* needed. The one-year-old just beginning to walk will appreciate an outstretched hand to support him. At a year and a half he will scorn the proffered help when walking on the level but perhaps welcome it on the stairs. At three or four he will probably resent any effort to hold on to him when he walks, except in crossing streets; but when he learns to skate, he will again welcome a supporting hand. Progress is often so rapid that the protecting mother cannot keep up with it. She is bewildered when the help that was eagerly sought a few weeks previously is now scornfully refused. Self-reliance and independence in the new activity must be attained before the learning can be considered complete, and these can be acquired only when the child is given freedom to try it alone.

"Health Habits." Eating, sleeping, and elimination are often designated as "health habits." Basically none of them are habits in the strictest sense of the term. They are fundamental biological activities which the child does not have to learn, and which he cannot unlearn and survive. All that training can accomplish is to enable him to avoid social conflict by limiting these necessary biological activities to socially approved times and places.

Sleeping occupies most of the newborn infant's time. During the first month, 80% of the day is spent in sleep. The baby wakes at frequent intervals from hunger, but when fed falls promptly asleep again. As the alimentary tract grows, more food can be taken at a time, hunger recurs less frequently, unbroken sleep becomes more prolonged, and the total amount of sleep required gradually diminishes. By the end of the first year, the baby spends only half his time in sleep, usually divided between a night's sleep and a morning and afternoon nap. At the age of eighteen, the average youth still spends about 36% of his time in bed.

Nineteenth-century moralists viewed prolonged sleep as a waste of time and exhorted boys to early rising. Today the biological importance of sleep as a period of recuperation is

so generally recognized that many parents go to the opposite extreme of trying to force children and youths to take more sleep than they require. It is a mistake to put pressure on children about their sleep. When this is done, sleep becomes an unpleasant duty to be postponed as long as possible. Relaxation is essential to sleep. A disciplinary conflict over going to bed promotes not relaxation but tension. Usually sleeplessness is just a symptom of tension. An effort should be made to discover and eliminate the cause of the tension rather than to enforce sleep.

The extent to which health depends upon adequate nutrition has been so widely publicized that many mothers become so nervously determined to feed their children that they defeat their own ends.

The battle for obedience, once centering around religious issues, now centers around eating in a definite sequence prescribed portions of spinach, egg, or carrots. A book or two on dietetics is popularly supposed to give the parent enough information to determine just what foods the child needs and just when and in exactly what amounts. As a matter of fact, dietetics is a very complicated field. Even a partial understanding of its problems requires years of training in chemistry, biochemistry, physiology, and other basic sciences. Fortunately all this knowledge is not required in order to feed a child satisfactorily. This task has been accomplished successfully by parents who could neither read nor write. The danger comes when the zealous parent mistakes half-knowledge for omniscience. The mother should by all means get as much scientific information as possible and offer the child whatever foods the dietitians recommend, up to the limit of her budget, but she should avoid undue insistence. C. M. Davis has shown that even newly weaned infants are capable of choosing foods that keep them in an excellent state of nutrition. When children lack appetites, it is usually because food has been forced upon them in such a way as to make it distasteful. Most undernourished children come from one of two groups, (1) the underprivileged for whom only a meager, monotonous, inadequate diet is provided, and (2) children of food-faddists who provide adequate meals but destroy their children's appetites.

Feeding problems most often arise because the child has been frightened or made angry during a meal. Loss of appetite under these circumstances is natural for a person of any age. Food eaten by a person who is emotionally upset is not likely to be properly digested. Therefore, forced feeding of a child is bad for his health. Moreover, it usually prolongs the feeding problem.

Forbidding a child to have anything else to eat until after he has finished a prescribed portion of some particular food practically amounts to forcing him. He may eat it today to escape the pangs of hunger, but the unpleasant experience is likely to create a permanent dislike for that food—an unfortunate bit of learning, if the food is really desirable. Some children are so hounded by anxious mothers that they acquire a distaste for every wholesome item on the family menu.

Loss of appetite may result not only from insistence on the eating of particular foods, but also from overstress upon table manners, or from the abrupt silencing of a happy, enthusiastic child who is eager to talk, or even from excessive efforts to help a child that is striving for independence. If the mother insists upon spoon feeding a child who is old enough to hold his own spoon, he sometimes becomes enraged; but if she lets him feed himself for a while, he may soon tire and want to be fed the rest of his meal. This is not inconsistency. It merely represents a change in the pattern of needs. The need to practice a new activity has been satisfied, but the need for food persists. Young mothers with tact and imagination can let the toddler feed himself while he wants to and take over the job when he tires; but those who are overconscientious about following a prescribed regimen of training procedures lack this adaptability. Mothers of children with feeding problems are often surprised when their children develop excellent appetites at nursery school, away from maternal pressure and solicitude.

Probably no phase of habit training has caused more trouble to mothers and children or paved the way for more serious maladjustments in later life than toilet training. Old manuals for mothers and nurses used to advocate beginning the infant's toilet training as early as possible, and many young mothers actually

developed a rivalry to see whose child could be trained first, sometimes beginning their efforts in the third or fourth week. Even with this early start, less than half attained bladder control by the end of the first year, and only about 80% by the end of the second year. It has recently been shown, however, that the training period can be greatly shortened with happier results all around, if the mother will postpone any training efforts until the child has reached a stage of physiological maturation sufficient to make real voluntary control possible. Gesell, Ilg, Thompson, Amatruda, McGraw, and others have stressed the importance of maturation as a prerequisite for all forms of learning.

The muscles of urination are among the very last to come under voluntary control. This must await the myelination of nerve fibers connecting the reflex centers at the lower end of the spinal cord with the cerebral cortex, an extrauterine embryological development which is ordinarily completed around the end of the first year. By the method of co-twin control, McGraw has shown that training begun at or after this time can be successful within a few weeks, whereas training begun in early infancy is ineffective before this stage of maturation is reached.

It is true that many mothers by observing a baby's natural rhythm and holding him on his pottie just before the anticipated elimination can manage to keep him reasonably clean and dry. This must have been the sort of "control" established in those cases in the White House Conference Material for which control was reported to have been established before the end of the first year. Surely mothers could not have meant that these infants on their own initiative went to the bathroom and managed their own clothing at an age when most infants cannot walk alone. The absence of accidents at this early age reflects the mother's vigilance rather than the child's. It does not necessarily have anything to do with real training.

A mother whose baby is "trained" in the sense of having a predictable biological rhythm to which she herself has learned to conform should be prepared for relapses when the child grows older—because the natural periods of urination will then be separated by somewhat longer intervals of time. Many a toddler when placed on his pottie fails to perform, only to wet himself a few minutes later. It is a mistake

to interpret this as a voluntary refusal. Punishing a child under such circumstances is a cruel injustice and may lead to serious results, reaching even into adult life. Punishment is not always physical. The mother who acts shocked or embarrassed or greatly disappointed in her child is punishing him. In fact to a child that loves his mother (and practically all children do), her emotional reaction is more effective than anything else she does. And what does he learn from her emotional reaction to accidents of this sort? He learns to regard the simple biological processes of defecation and urination as shameful in themselves. Because of shame, some children conceal these needs as long as they can, even to the impairment of health. Some cases of constipation are reported to have originated in this way.

Because of the anatomical proximity of the sex organs to those of elimination, sex prudery and many forms of maladjustment are believed by some clinical psychologists to have their roots in emotional traumata of the preschool period, frequently in connection with toilet training.

Young mothers who have kept their babies clean and dry by their own vigilance sometimes think the preschool child has regressed when he is not able to assume the responsibility for himself.

Actually, the real learning does not begin until the child is able to perceive the sensations of tension in rectum and bladder, interpret their meaning, and signify his need to his mother or some other adult, at first by grunts and gestures, later by words. In this stage of learning, freedom from accidents will depend upon the promptness with which adults understand and grant his request for the help needed. The building of an appropriate vocabulary early in the preschool period is very important. Adult prudery seems to prevent many parents from teaching their children the ordinary English words that could be understood by everybody. Some children who were completely trained at a year and a half, so long as they remained with their mothers, develop "enuresis" when they enter nursery school, kindergarten, or even first grade, because they either do not know how to tell the teacher their needs or are too embarrassed to do so.

Emotion. Emotional learnings inevitably ac-

company learnings of all kinds. The physiological basis of emotion is a part of the hereditary equipment of the species, but differences in emotional expression and in the objects and situations that arouse it apparently depend upon conditioning, chiefly in early childhood.

Desirable emotional development involves not only control over the more undesirable emotions but also the growth of self-confidence, social feeling, and a sense of belonging.

The emotional climate may be more important than any particular thing the mother says or does. Professional psychologists should therefore be careful not to discourage or antagonize young mothers, for in so doing they may increase the mother's anxiety, which is often the main source of the child's problem. Reassurance and encouragement of the mother and praise for her efforts may relax her tension, enabling her to take more joy in her child, and thus to give him the love and acceptance which are his greatest emotional needs.

Different observers have differed considerably in their reports on the apparent emotional life of infants. Watson thought that he observed in the new-born infant three emotions: love, fear, and anger. Bridges found only one: excitement. She reported that distress and delight are not clearly differentiated till about three months. By the end of the first year, several more emotions are distinguishable.

Watson reported that new-born infants have only two fears,—a fear of falling and a fear of loud noises. He accumulated evidence to show that all other fears are acquired in the course of experience. Any stimulus that becomes associated with pain or injury may become an object of fear, but the majority of fears are socially acquired. The young child tends to reflect his mother's emotional attitudes. This contagion of emotion serves to protect the toddler from real dangers while he is still too young to understand the nature of the danger. If the mother cries out in alarm or jerks him back when he starts to cross a busy street, he learns to be afraid of street crossings and wait for adult guidance. Similarly, he learns to shun poisonous snakes and snarling dogs without waiting for the costly experience of being bitten. Fear displayed by parents, siblings, or associates is sufficient warning. Conversely, if parents and asso-

ciates have foolish fears, the child will absorb these with equal ease.

It is a mistake to try to cure a child's foolish fears by ridicule. This simply leads to inferiority feelings and adds to the simple physical fear the much worse fear of fear itself.

Foolish fears can be gradually eliminated by familiarity with the feared objects or animals, provided no painful or frightening experiences occur while the familiarity is being acquired. For example, if a child is afraid of dogs, the fear will gradually drop away as he sees other children playing safely with them, and as he himself ventures a little nearer each day with no ill effects. On the other hand, efforts to force an immediate approach will intensify the fear.

Fear is such a powerful motivating force that parents and teachers of the past have made excessive use of it, often with disastrous results. Anxieties that undermine health, interfere with normal development, and sometimes persist into adult life, causing severe neurotic conditions, have been traced back to fears deliberately planted in childhood as a means of controlling some undesired form of behavior. For example, frightening warnings about the evil consequences of masturbation have been shown to cause more damage, mental and physical, than the habit itself could possibly have caused.

Just as danger, actual or imagined, is the stimulus for fear, so the stimulus for anger is interruption of the individual's activity. When the activity is directed toward the satisfaction of some biological need or the escape from real or fancied danger, then the stimulus for anger becomes a stimulus for fear also. Fear and anger commonly occur together. Either may lead to expressions commonly associated with the other. Flight is the normal expression of fear, but the cornered animal will fight. Parents who try to maintain discipline through appeals to fear are often bewildered at the number and variety of behavior problems that their children display. The misbehavior is commonly the child's way of punishing the adult who has frightened him or humiliated him.

Aggressive behavior is the normal expression of anger, but when the individual's anger is roused against someone he loves, he sometimes becomes afraid of his own impulses and shows all the symptoms of a severe anxiety attack.

Many unexplained illnesses of infancy and

childhood, especially digestive disturbances, probably have their origin in disciplinary conflicts with parents.

The surest way to arouse the anger of a baby is to hold down his arms and legs, impeding his movements. The need to exercise the growing muscles over which he is just beginning to gain control is a real biological need. Even in adults, prolonged restraint of movement can produce great discomfort, even severe pain, probably due to circulatory disturbances resulting from accumulation of venous blood that would normally be pumped back toward the heart by the pressure incidental to muscular activity. The baby cannot describe his pains nor state his desires. He can only scream and struggle. Tight clothing, tight bedclothes, and all forms of mechanical restraint should be avoided.

Throughout life, but most noticeably in early childhood, emotional reactions are reciprocally connected with the physiological condition. Cannon groups fear, hunger, rage, and pain together as the emergency emotions. Their occurrence prepares the organism for vigorous action, fighting or running, as the occasion may require, and temporarily interrupts digestion and certain other metabolic processes that can wait. This preparation for action includes increased blood pressure, more rapid heart beat, increased tonus of skeletal musculature, a pouring of adrenalin into the blood stream, and numerous other definite bodily changes. Now if the action runs its course, the emotion is ordinarily dissipated, taut muscles relax; the overworked heart slows down, peripheral blood pressure is diminished, blood flows back to the visceral reservoirs, the interrupted digestive processes are resumed, and the entire organism returns to its normal condition. But if the action is inhibited while the emotional stimulus continues to operate, then the state of preparation persists. Muscles remain tense, blood pressure remains high, digestion and assimilation continue to be postponed, while the undigested food putrefies in the alimentary canal, causing pain and distress, and adding more stimulus to fear. A vicious circle ensues.

In contrast to Cannon, who considered fear and anger to be practically identical physiologically, Magda B. Arnold finds evidence that they are as different physiologically as they are psychologically. Fear is characterized pre-

dominantly by sympathetic excitation; anger by strong parasympathetic excitation. Fear is enervating rather than energizing. Activity is diminished in moderate fear; in extreme fear, activity may be prevented altogether. Fear may be useful to the organism, not by preparing for action but by delaying action and enforcing caution. Vasoconstriction and rise in blood pressure are effects of sympathetic stimulation. A parasympathetic reaction commonly results. Arnold finds considerable evidence for a mechanism of alternative reaction, both nervous and humoral, so that extreme stimulation of either the sympathetic or the parasympathetic system will result ultimately in the reactive stimulation of the other. Whether the reaction becomes evident during the emotional stimulation or after it depends on the reactivity of the individual and the intensity of his emotional experience. Arnold contends that both anger and fear are obstacles to efficient action. The emotion which she finds most favorable for activity is *excitement* or *elation*, which is distinct from both anger and fear. Physiologically elation involves a moderate parasympathetic activity without any interfering sympathetic reaction.

Many parents, having heard that emotions of fear and anger are bad for a child's health, attempt to solve the problem by forbidding all outward expression of the emergency emotions, overlooking the value of emotional outlets for the relief of tension. Now it is of course important that even the young child learn to control his emotions. Indiscriminate striking, throwing, kicking, and biting can make him a nuisance to adults and a terror to other children so that he is denied all the satisfactions of being loved and accepted. On the other hand, a child that never takes his own part is not much admired either. Studies of children's attitudes toward aggressiveness in other children indicate that young children do not disapprove of aggressive behavior as much as mothers and teachers are prone to do. Quiet, timid, passive children are more likely to be social isolates than those that are normally aggressive. The goal of emotional training should be rational control and social effectiveness. The child should be helped to observe the outcomes of his own behavior in various types of situations. Through experience, supplemented by sympathetic adult interpretation, he can gradually learn that when he

fights a smaller and weaker child, he is scorned as a bully; but if he fights a larger and stronger child, he is admired. It is a mistake to try to inculcate the idea that fighting is always good or always bad. The capacity for fighting is part of everyone's biological heritage. Attempts to root it out entirely are usually ineffective, and if successful, they would weaken the individual for the struggles of later life.

Bullying of younger children may occur from various causes. (1) The bully is often a child that has been subjected to a great deal of punishment, rousing aggressive feelings which he dares not work off against the adults who have punished him. So he seeks a relatively helpless younger child as a scapegoat. (2) The bully may be suffering from jealousy because he feels that a younger brother has supplanted him in his mother's affections. (3) The bully may be suffering from inferiority feelings, sometimes due to school failure, and he may be seeking to bolster his self-esteem by displays of physical prowess. (4) The bully may have been formerly a weak and timid child, afraid of other children. His present aggressiveness may serve to prove to himself and others that old fears have been overcome. In any case, the first step in dealing with a bully is to seek the cause of his aggressiveness and then try to remove the cause or to provide less harmful outlets for his anger (if it is anger), or more constructive avenues to self-display. Sometimes a dangerous bully is no longer a problem if he is given opportunities to display his prowess in competitive athletics. Sometimes a social promotion to a higher grade will relieve the dull child who hates and bullies his brighter, younger classmates. Sometimes membership in a club of boys his own age will remove a jealous older brother from younger siblings over whom he tyrannizes.

At a fairly early age, a child can be taught that anger increases his available energy, and that this energy can be used for something he wants to do. Many a boy has learned to work off his temper chopping wood. Even the preschool child should have some toys that he is free to throw and a place in which he may throw them.

One therapeutic technique employed in some child-guidance clinics consists in having plenty of cheap play materials, especially dolls, encouraging the child to name the dolls after mem-

bers of his family, and then letting him do what he pleases to them. This seems to serve two purposes, (1) providing a harmless outlet for aggressive impulses, and (2) indicating to the psychiatrists just which family relationships are maladjusted.

Thinly veiled antagonism against one parent, typically the father, is so common as to have received a special name, the Oedipus complex, and to have become the subject of a copious literature. Freud attributed it to the boy's jealousy of his father in the rivalry for the mother's love. A more plausible explanation is the fact that the father is usually the punishing parent, many mothers preferring to delegate this unpleasant role to their husbands and some fathers finding in it a socially approved outlet for their own pent-up aggressions.

It used to be thought by all educators that the only way to inculcate a good habit was to punish every lapse, and the only way to break a bad habit was to punish every occurrence of it. Hence, it was taken for granted that much punishment during early childhood was an unavoidable phase of education. It has been shown experimentally, however, that rewards are more effective than punishments, and that when punishment is administered, the child is quite as likely to associate it with the punishing person, or the learning situation, or any incidental factor of the environment as with the act the adult is trying to punish. W. K. Estes has found that even with albino rats a response can not be eliminated more rapidly with the aid of punishment than without it. "In fact, severe punishment may have the opposite effect. A response can be eliminated only by a sufficient number of unreinforced elicitations, and this process of extinction cannot proceed while a response is suppressed as a result of punishment. . . . While it is suppressed, a response is not only protected from extinction, but it may also become a source of conflict." This gives experimental support to a conclusion for which much clinical evidence has long been available.

The emergency emotions are aroused only when the individual is inadequate, or at least feels inadequate, for the situation confronting him. Hence, the best safeguard against anxiety and hostility is to build up in the child a realistic feeling of self-confidence, based on experiences of success in progressively more difficult

undertakings. Every actual success increases the child's self-confidence. Every failure weakens self-confidence and lowers the level of aspiration. Hence, our suggestions and demands should be adapted to the individual child's actual abilities.

Intellectual and Linguistic Development. Curiosity is the most effective motivation for intellectual learnings. It appears spontaneously in infancy, increases throughout childhood, and finds expression both in exploratory activities and in the asking of questions.

The child's earliest ideas probably come from sensory experiences. Freedom to explore and manipulate at least some part of his own small world is important. Better a cheap toy that he may take apart to see how it works than an expensive one that he may not touch. Better still, simple constructive materials that he can combine and organize at pleasure.

During the first year, every toy should be suitable for sucking, easily sterilized, colored only with certified food colors, light enough for the baby to handle, and not small enough to be swallowed. For later years, one good rule is, "The smaller the child the larger the toy." Large muscles of trunk and limbs come under control before the smaller muscles. A child can push a chair around easily, long before he can guide a pencil with precision. Preschool children delight in building with large blocks and finger painting on large sheets of newsprint stretched over easels. A child's toy should be his own, to take apart and recombine as he pleases. Much of the so-called destructiveness of children is really exploratory experimentation. One theory of mental retardation is that it sometimes represents a disturbance of the exploratory function, caused by severe reproof or punishment for early exploratory activity.

Except for his own meager perceptual experiences, the young child's only source of knowledge is the information imparted by the older members of his family and his neighborhood. Whether this information is retained or forgotten depends largely upon whether it fits into the child's own growing pattern of ideas.

As soon as he is old enough to ask questions, he is old enough to have them answered simply, seriously, and truthfully. He may not understand all the answers, but if he does not, further questions will be elicited, and his

knowledge will grow. Anyone who ridicules a little child's questions discourages his efforts to gain knowledge. Moreover, the fear of being laughed at, planted by ridicule in early childhood, may persist throughout school and college, discouraging him from participation in recitations and class discussions, and preventing him from asking questions to have his difficulties cleared up. Profound discouragement and sensitiveness to ridicule may so retard mental growth as to simulate feeble-mindedness. Anyone who lies to a little child not only builds up confusions and misconceptions which must later be unlearned but also weakens his faith in adults. Parents who impose on a child with the stork myth need not be surprised if a few years later he takes elsewhere his questions about birth and sex and life.

Answers to the child's many questions must of course await his ability to formulate them in words that other people understand. Clear speech is an indispensable tool of intellectual communication. Adults can help a child learn to speak by speaking to him clearly, distinctly, and correctly. The use of baby talk by the adult delays the child's learning of normal speech and may expose him to needless ridicule later on when he goes to preschool or kindergarten. Simple words and short sentences should of course be used. Care should be taken to help the child associate the right word with the right thing. Concrete, perceptual demonstrations should accompany early language training whenever possible. Children of two or three delight in acquiring new words, and frequently point to things, asking "What's that?" The best early language training consists in answering such questions promptly and correctly.

At the opposite extreme from the baby-talking parent but equally disastrous to speech development is the parent who feels obliged to correct every childish error and make the child try again. This leads to self-consciousness and hesitancy in speech, and is thought by some to be a possible cause of stuttering, though other authorities attribute stuttering to a disturbance of cerebral dominance brought about when a left-handed child is forced to use his right hand. All babies and most preschool children occasionally repeat syllables, and this is not considered stuttering when it occurs before the fourth or fifth year. It is a normal phase of the

complex task of learning the motor sequences involved in speech. It occurs more often when the child is excited and worried than when he is calm and secure. Parents who make an issue of it tend to fix a transitory difficulty into a permanent one.

Though numerous writers report cases of stuttering arising when left-handed children are made to write with the right hand, Wallin, Parson, and Morsh, however, all find evidence that it is possible for left-handed children to learn to write with the right hand without any ill-effects on their speech. Apparently the harm is done not by the acquisition of a new skill but by negative teaching methods which make the child self-conscious and unhappy. If a child begins stuttering at any time from any cause, the best remedy is to stop picking on him, not only about speech and handedness but also about other things.

Individual differences in intelligence are apparent even in infancy, becoming increasingly evident with the development of language, and still more noticeable as children progress through school. Though no race, class, or socio-economic group has a monopoly either of genius on the one hand or of mental inferiority on the other, both casual observation and the results of mental testing indicate that the intelligence of privileged children averages somewhat above that of the underprivileged.

From the time of the early Greeks it has generally been recognized that both heredity and environment play a part in shaping the intellect of the individual, but the relative emphasis on the two has differed at different times and in different places. Aristocratic societies have generally emphasized heredity. The founders of democracies, by predicating their system upon fundamental human equality, seemed logically forced to assume that improved environment and education would lessen the obvious inequalities in human abilities. Hence, democracies everywhere lay great stress upon education.

But the extension of traditional school procedures to all children served at first only to bring the inequalities into sharper focus. Forcing a child of inferior ability to compete daily with brighter children who seem foreordained to excel him is one of the surest ways to make him chronically unhappy, rebellious, and per-

haps delinquent. The believers in equal opportunity were obliged to choose whether to give the children equal opportunity for liberty and happiness (the original goal) by adapting the curriculum to individual abilities and needs or to stick to the obviously disastrous program of identical schooling for all. The schools of France decided to take account of individual differences in intelligence. Alfred Binet, after more than fifteen years of research, gave the world in 1908 the Binet tests, a series of questions and problems, beginning with some easy enough for an average three-year-old, and continuing in groups of increasing difficulty up to tests hard enough for the average adult. The tests have been translated into many languages, restandardized for many national groups, and have been extended upward through three increasingly difficult superior adult levels and downward into early infancy. On the whole, they have been remarkably successful in enabling their users to predict school success not only in the immediate future but over a period of years. Their use has rescued thousands of feeble-minded and dull children from the daily humiliation of failure and made possible their education along lines suited to their abilities. It has also helped progressive educators to sort out superior children for special advantages. Rightly used, intelligence tests are an educational tool of inestimable value.

Unfortunately, some of the early popularizers of the mental test movement believed that they were measuring the child's hereditary endowment. Even when they asked him to define words and work problems in arithmetic, they still thought that they were measuring something hereditary and immutable. The argument was that since practically all the children given these tests had been in public school, they had had equal opportunity to learn the small amount of language or arithmetic required, and failures must be due to deficiency in learning capacity. To clinch the argument, instances were cited of children who had never attended school, yet made scores average or above average for their age. One such instance was a gypsy girl, who may quite possibly have had travel and exploratory opportunities more than compensating for the lack of schooling. Another instance was a boy from a superior home. The most extreme environmentalist would not deny

that the superior home might be a better place to acquire vocabulary and general information than the average school. For many years, a majority of psychologists accepted heredity as the only, or at least the most important, explanation for the failures of children who had been attending school regularly. Only gradually have we come to the realization that not all children sitting in the same schoolroom have an equal opportunity to learn. Some may be so preoccupied with personal matters that they give scant attention to what is going on. Some may need glasses. Some may be suffering from a temporary deafness due to enlarged tonsils or adenoids. Now the occurrence of enlarged tonsils and other anatomical anomalies may depend in part upon heredity, though focal infection is also important. In any case, prompt surgical care is largely a matter of family socio-economic status.

High correlations between the measured intelligence of children and the socio-economic status of their parents were early observed. These were interpreted as further proofs of the success of the tests in measuring hereditary intelligence. It was argued that the unintelligence of impoverished parents was what kept them poor, and conversely, that it was the intelligence of the well-to-do that had enabled them to get ahead. H. M. Skeels, however, has shown that average children when adopted into superior homes may attain the level of superior intelligence. In fact, Skeels found that there was less correlation between the intelligence of adopted children and that of their own mothers than between the intelligence of the adopted children and the presumed intelligence of foster fathers (estimated on the basis of occupational level), in a group of children adopted before the age of six months. H. M. Skeels, R. Updegraff, B. L. Wellman, and H. M. Williams did a controlled experiment on the effects of environmental stimulation in an orphanage preschool project. They found that the experimental group, those who were exposed to the stimulating preschool experience, made on the average measurable gains in intelligence, whereas the control group remained stationary or declined during the same period. There is a growing body of data to indicate that environmental factors may have more effect on the I.Q. than we used to suppose.

At the time when intellectual potentiality was thought to be largely fixed by heredity, the slow learner was considered hopeless anyhow, and hence, it was often recommended that he should leave school at thirteen or fourteen, after having spent the last few years of his school life learning some simple manual skills to help him earn a living. The quick learner was viewed as the hope of the world, upon whom the major educational effort should be spent.

Special classes for children of superior intelligence have proved their worth in New York City and several other places. The regular curriculum is mastered in about half the usual time, and the time thus saved can be devoted to a vitalized, socialized program constituting a real preparation for leadership.

Special classes for dull and defective children, though in existence longer and in more places, have been less successful, the main difficulty being that no matter what euphemistic names we may coin for them, there is no disguising their real significance from the children themselves. The very fact of being placed in such a class is regarded as a stigma and often exposes a child to the ridicule of playmates and siblings. Also, the purposes of these classes have been less constructively defined. In some cases, even the teachers view these children as hopeless, and conceive their teaching task to be simply one of maintaining order and keeping the children busy at something—no matter what—until they are old enough to leave school. In many places, a child is not assigned to one of these special classes until after he is at least three years retarded in regular school. By that time he is profoundly discouraged, and has sometimes adopted the attitude that regular schoolwork will be forever beyond his powers.

Intelligence tests given in the first week of school would make possible the tentative classification of children before reading and other schoolwork were begun. Since failure commonly lowers the level of aspiration, creates inferiority feelings, and sometimes leads to envy and hostility directed against more successful classmates, every possible effort should be made to protect a young child from starting a subject until he stands a reasonable chance of success.

Reading readiness depends upon physiological maturation, sensory adequacy, and a variety of previous learnings. The child's vision should

be tested shortly before reading is begun, to make sure not only that the acuity of each eye is adequate, but also that both eyes function well together. Binocular coordination often matures late, sometimes as late as the eighth or ninth year. The repetitions and reversals that so puzzle teachers are sometimes due to the fact that the child actually sees the same word in two different places on the page, the image from one eye being projected a little to the side of that from the other, and sometimes a little above or below as well.

Hearing acuity is also important to reading readiness if the phonetic method is to be used. It is not enough that the child understands spoken language well enough to obey simple commands. Many partially deaf children learn to interpret correctly the little that they do hear. Adults around them may not suspect the degree of auditory handicap. In some instances, hearing is cut off only in the upper register, so that the child hears vowel sounds correctly but does not hear *s* sounds or *f*'s. In ordinary life situations, the child may guess the meaning of words from the context; but in abstract phonetic drills, he is utterly lost. If the auditory defect is recognized, different teaching methods may be substituted, and the child may learn to read satisfactorily. But if the defect is not understood, the child is usually regarded as stupid, and may soon accept this verdict himself, so that he stops trying.

Besides vision, hearing, and other physiological factors, reading readiness presupposes many previous learnings. Comprehension of meaning rather than mere word calling is the goal to be sought. This implies that the words used in the reading lesson shall already be a part of the child's vocabulary, not just as words repeated after the teacher, but as significant symbols, rich in apperceptive associations. Meanings are built up gradually on the basis of concrete experience. Walks, games, trips in automobiles, trains, and ships, visits to museums, zoos, stores, railroad stations, farms, and factories all help to enlarge a child's stock of ideas. Children from privileged homes are more likely to have had at least some of these opportunities than underprivileged children, many of whom remain day after day and month after month in the same neighborhood without seeing anything that appears to them very new or significant. The chil-

dren of the privileged often spend one summer at the seashore, picking up shells, watching ships, and playing in the surf; the next summer in the mountains collecting pine cones and interesting rocks; and perhaps the next at a children's camp, under the guidance of college-student counselors. To each new school year such fortunate children bring a wealth of new ideas that put more meanings into their books. For the less privileged, the school should supply some of this concrete experience. In cities with museums, teachers can take their entire class to the museum. In the country, the entire class can go on a walk with the teacher along to answer questions and point out interesting things to observe. Sound-motion pictures can almost bring the world into the classroom. Sandtable miniatures are also valuable, enabling the child to comprehend as wholes the things that in actuality are so big he can only see them piecemeal.

Concrete perceptual experiences should be supplied in addition to the formal exercises in reading, writing, and arithmetic throughout the child's school experience. They also supply the answer to the question as to what sort of schoolwork is most suitable for children not yet mature enough to undertake reading with any reasonable hope of success. Particularly if the immaturity is an intellectual one, a program of concrete, meaningful experiences to build up vocabulary and interpret the child's world for him will help to get him ready for the day when he will be able to learn reading.

Another thing that can be done is to build up motivation for reading. Privileged mothers with leisure commonly begin reading aloud to their children when they are only two or three years old, pointing to pictures and interpreting them. Underprivileged women, overburdened with housework, washing, ironing, cooking, and often employment outside the home, may not find any time to read aloud. The child who is read to learns to think of books as pleasant sources of entertainment and to look forward to the time when he will be able to read for himself. This motivation for reading can be built up by the teacher even in children who will not be mature enough to read to themselves for another year or two.

The dull child attains reading readiness much later than his brighter classmates, but experi-

ments have shown that if formal instruction is delayed until reading readiness has been attained, the traditional failures can be eliminated. Reading begun late and pursued with success can be as pleasurable to the dull child as to anyone else. His slower learning rate necessitates devoting more time to repetitive drills, which are quite unnecessary for superior children, and new material must be introduced more gradually to avoid confusing him. Thus, instead of spending fewer years in school than the average child, the children of dull and borderline intelligence should be allowed more years to acquire the minimum of reading, writing, and arithmetic essential to successful living in our literate society. With such a school program, the majority of high-grade morons, many of whom are now supported in institutions for the feeble-minded, could be educated in the public schools and prepared for happy, useful lives in the community.

Binet's predecessors sought to devise separate tests for memory, imagination, reasoning, and other "mental faculties." By emphasizing general intelligence, Binet provided a short cut to practical results.

More recent advances, however, have come through analysis of "general intelligence," as measured by tests, into several component abilities, largely by the technique of factorial analysis.

Revived emphasis upon separable factors in intellectual functioning gives the educator some cue as to how to search out and alleviate the condition that is holding back the intellectual growth of a particular child. For example, Sarah Stinchfield Hawk finds that by remedial speech training she can facilitate general intellectual growth to such an extent that large sudden increases in I. Q. occur. This ought not to surprise anyone who is aware of the extent to which language is fundamental not only to social communication but also to private thinking.

G. D. Stoddard defines intelligence as "the ability to undertake activities that are characterized by (1) difficulty, (2) complexity, (3) abstractness, (4) economy, (5) adaptiveness to a goal, (6) social value, and (7) the emergence of originals, and to maintain such activities under conditions that demand a concentration of energy and a resistance to emotional forces."

Stoddard finds evidence that the development of intelligence, as thus defined, is determined in large part by cultural conditions. He contends that the "possibilities for human development through educative means are far greater than our ancestors supposed."

CLIMATE AND HUMAN BEHAVIOR.—That human behavior should be related in any fundamental way to climate will appear to many psychological readers as surprising, if it does not meet with out-and-out incredulity. This situation is only natural, for psychologists have been unaccustomed to noticing the efforts and suggestions of investigators far removed from their own field who have worked on the problem. Yet these investigators have been many since ancient times, and in the twentieth century there are three extensive projects in this country bearing on the subject, all well outside the boundaries of psychology. There is in addition a fourth, the "Kansas project." All of these projects involve psychology, but the fourth is the only one of its kind as yet undertaken by a psychologist.

The problem came to the attention of his-

torians, travellers, slave dealers, military officials, physicians, geographers, and other scientists of ancient Greece, among them Herodotus and Aristotle. Since then hardly a century has passed without its representatives who kept the suggestion alive. Nevertheless, but few in modern times have taken the matter seriously. Up to the present the problem was largely confined to the differences between peoples living in the warmer *versus* the cooler countries. Interestingly enough there has always been a striking agreement regarding these differences. People in warmer countries were said to be more timid, smaller, physically weaker, less courageous, but more inclined to physical pleasures, sexual indulgence and abnormalities; less aggressive, more effeminate, more sensitive, more irritable, more unstable emotionally, more cruel, more conservative; more addicted to immutable laws, to stubbornness, despotisms, and tyranny; more suspicious, more inclined to introspection; more mystical and melancholic; more likely to develop an economy based on slave labor; less conscious of the individual in the social group and hence less considerate of his importance and worth.

On the other hand the peoples and races of cooler countries in more northern regions or at higher altitudes were said to be more vigorous, aggressive, persistent, larger, stronger physically, healthier, gayer, braver in battle, less prone to sexual indulgence but having a higher birthrate. They were more tolerant; treasured liberty more; were more difficult to conquer and to keep under submission; were more democratic; were averse to slavery; they were more honest, trustworthy, less suspicious, more puritanic, more frank, less mystical, less given to reflection, and were more provident in their habits, in short, their traits were on the whole the exact opposites of those found in the warmer countries.

Jean Bodin, famous for his pioneer work in political science in the sixteenth century, made note of these differences, but little attention was paid to the problem again until the eighteenth century. John Arbuthnot, in 1733, said in an "Essay Concerning the Effect of Air on Human Bodies" that governments were "powerless to change the genius and temper of a race against the force of air and climate." In 1748 Montesquieu, in his "Spirit of the Laws," emphasized the problem. Statute laws, he insisted, should

be made to fit the character and temperament of different peoples differently conditioned by the climate in which they lived. In 1743 Buffon, the naturalist, also recognized the situation, and Adam Ferguson, in 1868, evidently influenced by Montesquieu, included a discussion of the subject in his "History of Civil Society." He believed that a temperate climate was the best for mankind, for it produced superior traits on account of its effects on human physiology.

During the nineteenth century a considerable amount of literature was published. Arnold Henry Guyot, a Swiss geographer who migrated to this country, contended in "Earth and Man, Comparative Physical Geography" that the temperate zone was superior both for the physical and social evolution of man. He thought that the changes of the seasons had much to do with the greater vitality that produced superiority in the races of the cooler but not too cold countries. During the middle of the century, Karl Ritter, a Berlin geographer, advanced a geographical interpretation of history in which climate figured in an important manner. His influence led to a school of environmental determinism. Henry Thomas Buckle recognized the problem in 1862 in "The History of Civilization in England," and in 1863, John W. Draper, an eminent American scientist and historian, said that "Where there are many climates there will be many forms of men. . . . For every climate and, indeed, for every geographical locality, there is an answering type of humanity."

Coming now to the twentieth century, Ellen Semple, a student of the Leipzig geographer, Friedrich Ratzel, agreed in general with the long observed differences between northern and southern races and concluded that climatic conditions gave a certain zonal stamp to human temperament and development. Robert DeCourcy Ward, 1902, in "Climate, Considered Especially in Relation to Man" was apparently convinced that this factor is one of the most important of all in the control of human development. J. Russell Smith wrote an "Industrial and Commercial Geography" in 1913 in which he said that cooler climates were a greater stimulus to the activities of nations and races and observed that the larger, more industrialized and aggressive cities of the world were for the most part located between thirty and sixty degrees north latitude. "To an extent little real-

ized," he commented, "environment makes the race."

In recent years Henry L. Moore and Edgar Lawrence Smith, interested in economic and production problems, have pointed out correspondences between economic and certain kinds of climatic fluctuations. In "Tides in the Affairs of Men," in 1939, Smith wrote, "Within the economic pattern of a period, the tidal ebb and flow of mass psychology in response to the rhythms of environmental change cannot be safely disregarded. . . . We need to know much more than we do about these natural rhythms and about the means by which they influence the moods of men, their hopes, their fears, their energies and their lassitudes."

Were all these investigators wrong? Were they crazy? Obviously not. It is patent to any intelligent person that different climates produce different fauna and flora. Why then should they not produce different kinds of people? Yet broach the subject today to many a scientist and one will immediately elicit a blank look of incomprehension, or one will be regarded as a crackpot fit only for the company of astrologers, palmists, and Hindoo prophets!

Not, however, in the estimation of Ellsworth Huntington of Yale, geographer and climatologist, and author of some twenty-eight books and numerous papers all having to do more or less with the influence of climate on human behavior and destiny. Among the more relevant of his works are "Civilization and Climate," "Palestine and Its Transformation," "The Pulse of Asia," "World Power and Evolution," "Environment and Racial Character," "The Season of Birth," and lastly, in 1944, "The Mainsprings of Civilization." His is project number one in this country, begun early in the century.

According to Huntington, climate exerts a strong influence on human behavior, including intelligence, aggressiveness and capacity for work. There is an optimum belt of storminess which, associated with temperatures that are not too extreme, is conducive to better health and higher energy levels. Ozone, he thinks, acts as an important stimulant. The month of the year in which one is conceived is also important. Reproductive vitality is at its height in spring and at its lowest level during the heat of midsummer. In the past, civilizations have sunk into decline, have died out, or the people were forced to migrate, because of changes in climate.

Dr. Clarence A. Mills heads the second extensive project in this country, at the University of Cincinnati Medical School. His two most important books are "Medical Climatology" and "Climate Makes the Man." Extensive studies of mice bred under artificial climates demonstrate that temperature is an important factor in conditioning size, body form, and fertility. High outside temperatures produced a tendency to expand radiation surface. Because the body must be kept at a relatively constant temperature inside, in the presence of high outside temperatures the organism must live more slowly physiologically and remain less active, otherwise body heat cannot escape as rapidly as it is generated and in time fever or death would result. On the other hand, the mice living in lower temperatures underwent a contraction of body surface in relation to weight, an adjustment resulting in more conservation of body heat. Energy level, Mills found, was a function of the ease of maintaining internal body temperature against excessive heat or cold outside.

Here we evidently have the cue of the differences in the behavior patterns of races or peoples living in warm *versus* cool climates. Tropical races have remained relatively primitive. Under conditions of excessive heat, evolution and growth potentials have been cut down. These people lack the vitality to put into their aggressiveness the drive, either mental or physical, possessed by cool climate races.

The third project which continued for a great many years was under the direction of Dr. W. F. Petersen of the University of Illinois Medical School, who wrote a four-volume work on "The Patient and the Weather." As in the case of Dr. Mills, he has done a great deal of statistical work correlating the incidence of different physical and mental diseases with different weather and climatic conditions. Recently he published a very interesting little book, "Lincoln and Douglas, the Weather as Destiny," one implication of which is that introverted personalities stabilize on rising temperature curves and extrovert personalities on falling temperature curves. This is not in the least fantastic.

The fourth project, the one at Kansas, is in its fourteenth year. It began purely by accident when a review of the history of psychology resulted in noticing that the antecedents of Gestalt

and association theory alternated with one another down through the centuries, simultaneously with corresponding shifts in point of view in biology and philosophy. This fact led to a study of the other sciences, then of the arts and literature, then of the political and military history of all the known countries and peoples of the world beginning with ancient times. Up to this point the investigation had resulted in a curve depicting the relative prevalence of individual cultural products, all of which naturally fell into two categories, the one organic and the other mechanistic or atomistic. A culture pattern representing all important phases of human activity was fluctuating back and forth in rhythmic fashion as a vast, complex, but integrated whole or Gestalt, each detail of which was related logically with the others in so intimate and clear a manner that, knowing one of them, the others could be predicted. The major rhythms averaged about 100 years in length but clustered into groups of five, beginning with the middle of the sixth century B.C. The terminations of the 500-year rhythms occurred near the death of Caesar and the turning point in the vitality of the Roman empire; in the fifth century (fall of Rome and its contemporary ancient empires), the tenth (ending the first half of the Middle Ages), and the fifteenth (the fall of the second half of the Middle Ages). The termination of the present 500-year period is due around 1980!

The manner in which climate came to be involved was another accident. While inspecting the culture curve a colleague remarked that it resembled the California sequoia tree ring curve which goes back to 1350 B.C. The author of the project had never heard of such a curve. On investigation it was found that the two curves resembled one another in a manner that could not possibly have been explained by chance. This led to the assumption that the culture fluctuations could have been climatically conditioned, but the culture curve represented practically all of the civilizations of the world, past and present. Was there such a thing as a fluctuating world climate? Huntington had suggested an affirmative answer but no exhaustive work had ever been done in an effort to trace the history of climate over the world as a whole, as far as it could be known. No one had even made a complete comparative study of temperature and rainfall curves as far back as

they go for the world as a whole. The only approximate attempt was made by Brückner in 1890. Accordingly, many years have been occupied in obtaining as complete a picture of the history of climate as possible and the work is yet far from finished. However, the data are complete enough to justify the statement that unless the cultural fluctuations are climatically conditioned, the coincidences violate all the laws of chance and are utterly inexplicable in the light of our present knowledge.

The data warrant the conclusion that there is a world climate, although never completely homogeneous in character; that this world climate has fluctuated in rhythms within rhythms which tend to follow the multiples of the sunspot cycle of 11.3 years; that these rhythms whether long or short tend to follow a similar pattern of phase sequences, the phases being cold-dry, warm-wet, warm-dry, cold-wet, then cold-dry again, in that order.* The 100-year and 500-year climatic rhythms correspond with the culture rhythms already mentioned. Shorter climatic and cultural rhythms superimposed on the longer ones also correspond, frequently down to the single sunspot cycle.

Space does not permit explaining in detail the sources of information regarding the history of climate prior to measured temperature and rainfall. A partial list must suffice: tree rings, lake levels, river levels, drought and flood chronologies from different localities; famines, crop failures, harvesting dates, ice-forming and ice-breaking dates, early and late frosts, reports of excessive heat, cold, storms, snow; clay varves; travel through mountain passes; the receding and advancing of glaciers; formation of bogs; pollen analysis; expansion and contraction of arid regions; data from military posts, monasteries, government records and numerous diaries; data from accounts of campaigns that ran into extreme weather; locust plagues; types of vines and other vegetation; sunspots large enough to see with the naked eye and aurora (both known to be associated with drops in temperature or with cold periods); lengthening and shortening of the sunspot cycle, etc.

Even though individual items run into the

tens of thousands, there is no way of telling what the average temperature or rainfall was during a given period, but it is possible to locate the phases of the 100-year cycle beyond much question, and in many instances the phases of shorter fluctuations.

Assuming this picture to be reasonably correct, there is no question but that nations or empires rise and fall on tides of climatic change. Dated international and civil war battles from over the known world since 600 B.C. obtained from around 250 volumes of history, and plotted against the curve, fall so consistently during the warm and cold phases, respectively, or overlap on the transitions from warm to cold or cold to warm, that these battles alone would have located the warm and cold phases of the 100-year rhythms as well as most of the interruptions (smaller superimposed rhythms), if the interruptions were as long as ten years.

The so-called Golden Ages of history generally occur on the transition from the cold to the warm phase of a 100-year cycle which has all of the appearances of being a high energy-level time in history. Occasionally a Golden Age will occur on the transition from warm to cold, but evidently only under certain special circumstances which cannot be discussed here. Never do they occur during the hot-dry or cold-dry phases. Out of 55 sovereigns who have come down through history with the title, The Great, 48 have ruled on this transition. Of 650 rulers, about half of whom the historians characterize as good and half poor, 80 per cent of the good, in the world as a whole, have ruled at the close of a cold and opening of a warm phase. Over ninety per cent of the poor rulers divide almost equally between the hot-dry and cold-dry phases of the cycle. The transition from cold to warm is nation-building time the world over; and the transition from warm to cold is nation- or government-falling time. These correlations hold even for the warrior states of Africa and the East Indies. They hold for the Orient as well as for the Occident, and for the Indian civilizations of the western world in so far as data are available. It should be kept in mind that we are discussing world trends. From time to time there have been lags and leads both in the climate of particular regions and in the shifting of the culture pattern. No known exceptions of any consequence have yet

been found, although there are instances in which the data are incomplete. Where nothing is known of the prevailing climate in a particular country at a particular time, the chances of that country not following the general trend of the 100-year cycle are practically nil. But the summation of all possible exceptions would not materially change the nature of the correlations, for reasons that cannot here be discussed.

Many other types of culture variables are distributed along the climate curve so consistently that any one of them could be used as a criterion of the warm and cold phases of the 100-year cycle. For example, dated migrations regularly cluster during major cold-dry phases from the sixth century B.C. to the nineteenth century. Sometimes they begin, as one might expect, during the preceding hot drought and continue into the cold phase, but they consistently disappear during warm-wet phases when water and food are abundant and nomadic peoples can remain in one region or even build towns or cities. Another example is Baroque art, which is consistently a cold-phase phenomenon.

The types of cultural events that consistently cluster during the various phases of the climatic cycle are shown on the following pages.

The highly integrated character of the culture pattern loses its mysterious character when it is seen that the atomistic or cold-phase pattern in every respect emphasizes the part of anything at the expense of the whole, while the warm-phase, organismic pattern emphasizes the whole of anything at the expense of the part. With a little study of the lists in the table this fact should easily become apparent. It is not so strange, therefore, that algebra is cold and geometry warm; that the cell theory and its antecedents are cold and epigenesis warm; that encyclopedias are cold; and systematic, integrated works, warm.

The hot drought phase is the typical season for despots, dictators, communism, totalitarianism, Gestapos, pogroms, fascism, and decadence in general. And what more logical explanation could there be than that through devitalization from the effect of temperatures much higher than those to which they have been accustomed, people have become irritable and unstable or lethargic and indifferent, depending upon circumstances? Similarly it would seem obvious

that the Golden Age period occurs where both temperature and rainfall and sufficient variability in humidity and temperature following a revitalizing cold period have raised the human energy level to its maximum, along with conditions adequate for economic prosperity.

Patterned after the experiments of Mill on

mice raised in artificial climates, rats were studied for four generations in the psychological laboratory at Kansas. Hellmer divided several hundred newly weaned white rats into three colonies. As nearly a third as possible of each litter was placed in a room of 90 degrees constant temperature, another third in 55 degrees,

and one third at ordinary room temperature. When the rats had reached the age of twelve weeks Hellmer studied their performance in a simple, four-alley maze with the following results:

TABLE 2*
1ST GENERATION

Group	No.	Trials Mean	Errors Mean
Cold	49	21	133
Control	45	26	149
Hot	35	54	297

2ND GENERATION			
Cold	43	22	135
Control	46	29	156
Hot	36	48	269

* See Hellmer, L. A., "The Effect of Temperature on the Behavior of the White Rat," *Amer. Jour. Psychol.*, Vol. 56, 1943, 408-421.

Moore subsequently repeated Hellmer's work, obtaining essentially similar results, and then moved one third of the "hot rats" to the cold room with a delay period in the control or "normal" room, one third into the control room, and kept one third in the hot room. The cold-room rats were treated in a corresponding manner, while one third of the control rats were moved to the hot room and one third to the cold room. After the rats had lived in their new environment thirty to forty days, they were tested in the maze for relearning. Moore's results were as follows:

TABLE 3*

Group	Mean of Trials	Mean of Errors	Number
Cold rats			
a. In cold room	7.1	17.4	14
b. In control room ...	9.8	31.8	17

b. In control room ...	10.5	36.5	15
c. In hot room	16.5	47.6	14

* From Moore, K., "The Effect of Controlled Temperature Changes on the Behavior of the White Rat," *Jour. Exper. Psychol.*, Vol. 34, 1944, 70-79.

In a period not longer than forty days the hot rats moved to the cold room approached the performance of the cold rats, and the cold rats in the hot room approached the performance of the hot rats.

The behavior patterns of the hot and cold rats were very different, and differences in body structure agreed with Mill's findings on mice. The differences in the two patterns of behavior showed many resemblances in a general way to the recognized differences in the behavior of warm- and cool-climate peoples, even to their sex behavior. The hot rats noticed each other more as evidenced in sniffing, regardless of sex, or whether the female was in heat, yet were less interested and vigorous during mating time; while the cold rats were far more "modest," yet more vigorous at the appropriate time. The litter rate in the hot room declined rapidly until sterility was so prevalent that the colony had to be replenished. Litters and progeny were small—the rats themselves were much smaller. In the second generation two litters a year were average. In the cold room, litters were much larger and averaged between four and five a year.

The hot rats were relatively vicious, bit their keepers occasionally under no apparent provocation, were erratic in the maze, showed many "neurotic" traits, frequently mutilated or ate their young, and were little interested in raising them. Opposite "traits" characterized the cold rats.

From these results it was concluded that temperature has much to do with the conditioning of the organism's vitality or energy level, hence its intelligence, aggressiveness, stability, and many other characteristics.

One aspect of the Kansas project has to do with efforts to predict the general trends expected in the immediate future, both climatic and cultural. The data indicate that we have just completed a warm phase which began in the neighborhood of 1900 (the last cold phase began around 1830 and lasted with interruptions to 1895 or 1900. The preceding warm phase began around 1790 and, with a break centered on 1815, lasted until 1830.) The last hot drought phase of the 100-year rhythm centered in the first half of the 1930's and brought with it the usual epidemic of dictators, depressions, and decadence. The data indicate that we

are in the cold-wet phase now; that the "bottom" of the temperature and rainfall curves for the world as a whole should be reached in the 1980's in which a severe cold-drought should center; that there is a good chance for an interruption of the cold period and a shift to the warm side for possibly as long as ten years in the 1950's or 1960's, but that the next main ascent to the warm side should not occur until around 2000 or 2010 A.D.—the next major nation-building age of history. The variables in the table constitute in each case an experimental "prediction."

Human ecology is bound to be one of the important branches of science in the future. World leaders of today should be cognizant of the fact that an intensive study of the climate of the past will ultimately lead to accurate predictions of trends far ahead into the future, and that the climatic phases of the future will probably produce the same types of cultural and behavior problems as they seemed to have produced in the past, over and over again, by controlling man's vitality or energy level. Much can be done by way of guaranteeing world peace when the underlying causes for man's temperament, aspirations, and changes in mood are realized. Specific problems can be anticipated in advance and solved before social forces get out of control. Moreover, universal air-conditioning should be helpful in making people more alike, thus leading to better mutual understanding!

RAYMOND H. WHEELER
University of Kansas

CLINICAL PSYCHOLOGY.—Clinical psychology is the scientific study of the mental processes of individuals in need of diagnosis and therapy because of symptoms of intellectual or emotional maladjustment. The closest proximate disciplines are those of neurology and psychiatry on the one hand, and education and sociology on the other.

The first test instruments devised for use in this field were intelligence scales for sorting out individuals of such inferior ability as to be in need of segregation either in institutions or in special classes. When these intelligence scales were applied to the task of measuring the ability of individuals already segregated as feeble-minded, it was found that all levels of

ability were represented among those adjudged to be feeble-minded because of persistent behavior disorders. On the other hand, many individuals in penal institutions were found to earn feeble-minded ratings, and to be in need of permanent guardianship.

As the need for finer measurement was felt, the scales were revised, extended at the upper levels and refined. This process still continues.

The Binet-Simon Scale in its various translations and revisions was welcomed as a god-send, but soon demonstrated its limitations as well as its sphere of usefulness. Following the construction of a variety of non-verbal tests, the Pintner and Paterson Scale of Performance Tests was constructed in an effort to organize these separate ratings into a single one with greater meaning. Successive performance scales have been constructed with improved statistical method resulting in increased predictive value. This process, also, still continues.

As studies of normal child development were carried out with increasing care for detail and accuracy of observation, new norms were obtained for evaluating the behavior of clinical patients.

The standardization of batteries of tests of school achievement offered a new means of evaluating the relative strength or weakness of the clinic patients in various school subjects. To these were added tests of mechanical ability in the hope of finding a field in which the maladjusted individual could make a comfortable adjustment. It was soon discovered that mechanical aptitude was less important for many individuals than mechanical interest. This discovery was followed by the construction and publication of a variety of "interest tests."

In the meantime, an effort was being made to measure certain behavior tendencies along with their emotional concomitants, objectively. This was attempted by obtaining a large number of subjective judgments from an individual. The classification of these responses yielded results that frequently were more revealing than any single subjective statement would be likely to be. As norms became better standardized, the results became increasingly valuable. A refinement of this kind of questionnaire is the card-sorting test of the type of the Multiphasic Personality Schedule which yields responses that fall into different patterns for different types of individuals and for different kinds of mental

disorder. These patterns are of interest in studying differences of emotional and behavior pattern in different cultural groups, and are of practical use to the psychological clinician in revealing tendencies toward abnormality of thought, feeling and behavior, in adolescents and in adults of both sexes.

The ink-blot test was used as early as 1895. It was organized as a clinical instrument by Rorschach. In 1930 Beck reported *Personality Diagnoses by Means of the Rorschach Test*. The clinical psychologist can now compare ratings on two standardized tests for individuals in whom marked deviations from the normal personality are suspected.

During the first years of measuring objectively and quantitatively the most easily observed characteristics of mental ability and disability, psychologists were preoccupied with the growth process and the successive steps leading to mental maturity. Clinical psychologists were often aware that their measuring instruments were not suitable for use with many adults, especially those with little education and limited experience. Babcock in 1930 reported an experiment in the measurement of mental deterioration, and in the same year Conrad published a report on the decline of intelligence. Other reports followed. In 1939 the Wechsler-Bellevue Scale presented norms of deterioration comparable to the norms of growth in common use.

With the development of scales for measuring different kinds of abilities, clinical psychologists have attempted to identify patterns of success and failure that tend to accompany specific types of behavior in life situations. The clinical value of many tests has been enhanced by reports of this kind of observation.

The work of the clinical psychologist supplements and is supplemented by that of the neurologist and psychiatrist, the school and the social worker. He observes the same phenomena as those working under these other disciplines. His special field is the measurement and statement in quantitative terms of facts observed and reported in subjective terms by other observers; and the interpretation and generalization, based on an accumulation of quantitative data (norms) of the facts that he reports. This interpretation and generalization constitutes both diagnosis and the basis for therapy.

The psychiatrist bases many of his judgments upon subjective norms built up through years of experience. The clinical psychologist bases many of his diagnoses on just such subjective norms in fields where quantitative data are lacking. However, it is the aim of the clinical psychologist to replace subjective norms with objective norms as rapidly as possible by the accumulation of quantitative data obtained under controlled experimental conditions.

GRACE ARTHUR,
St. Paul, Minn.

COLOR.—Color is a visual sensation normally produced when certain electromagnetic waves stimulate the retina. The longest visible rays are red of about 760 mμ. The shortest are violet. The shortwave limit of visibility is usually given as about 385 mμ, but W. Friedrich and H. Schreiber have recently (1943) reported that for young adults (17 to 30) it approaches 313 mμ and that for young children (around 6 years) the short-wave visible limits lie between 297 and 302 mμ. Thus it is probable that young children see radiations invisible to adults.

The color seen depends upon the wave lengths reaching the eye and also upon the condition of the retina at the time. "White lights" are mixtures of different wave lengths. By means of a prism and in various other ways, the component wave lengths may be separated and each of these appears brilliantly colored. Different "white" lights vary considerably in physical composition. Skylight at noon is often taken as the standard. This is bluer than direct sunlight and much bluer than most artificial sources of illumination. Yet the eyes ordinarily adapt to changing illumination so that few alterations in the colors of most objects are noted.

When an opaque object reflects skylight or sunlight without altering the proportions of the wave lengths in the visible range it is white. If it absorbs all rays falling upon it, it is black. If it absorbs some and reflects others, it is colored. The more nearly homogeneous the reflected rays are, the most vivid or saturated is the color.

If a body between the eye and the source of light permits all the visible rays to pass unchanged, it is transparent and colorless. If it reflects or absorbs some rays and permits others

to pass, it is colored, and the color frequently appears to extend throughout its depth, becoming a tridimensional or bulky color.

David Katz has called attention to the fact that colors as commonly seen have various spatial and textural qualities. He recognizes three main groups: (1) surface colors which appear to be located on the surface of some object and to partake of its physical texture, (2) bulky colors (*Raumfarben*), which appear to have definite tridimensionality, such as colored liquids and glowing coals, and (3) film colors (*Flächenfarben*), which appear soft and hazy, with neither definite depth nor definite superficiality. The blue of the sky is a typical film color. So is the gray or brown field of the closed eyes. Any color can be made to appear soft and filmy when viewed through holes in a screen, cutting off the normal kinesthetic cues to localization and objective reference.

Spatial and textural qualities then disappear, and colors vary only in three attributes: hue (called also color-tone), brilliance (called also brightness, luminosity, value, and tint) and saturation or purity (called also chroma).

The principal spectral hues arranged in order of decreasing wave length are red, orange, yellow, green, blue, and violet, though many intermediate hues have been distinguished and named. The range of wave lengths for different hues has been variously estimated by different observers. Abney's estimates were: red, end to 620 m μ ; orange, 620 m μ to 592 m μ ; yellow, 592 m μ to 578 m μ ; green, 578 m μ to 500 m μ ; blue, 500 m μ to 464 m μ ; ultramarine indigo, 464 m μ to 446 m μ ; violet, 446 m μ to end. Listing's estimates were: red, 723 m μ to 647 m μ ; orange, 647 m μ to 585 m μ ; yellow, 585 m μ to 575 m μ ; green, 575 m μ to 492 m μ ; blue, 492 m μ to 455 m μ ; ultramarine indigo, 455 m μ to 424 m μ ; violet, 424 m μ to 397 m μ . In a continuous spectrum, the different hues appear to merge into each other with no sharp line of division between them. It is impossible to say exactly where one color ends and another begins.

Nevertheless, four hues seem more fundamental than the rest: red, yellow, green, and blue. In every language, the names of these colors are so old that the objects from which the names were derived are forgotten, whereas for most other hues, such as orange, violet,

indigo, peacock, verdigris, etc., the only color name is the name of some fruit, flower, plant, bird, mineral, or chemical. Moreover, in popular speech, the names of the four principal colors, red, yellow, green, and blue, are used in describing all other colors.

Both physicists and psychologists commonly refer to homogeneous radiation of any visible wave length as "monochromatic" light because from a physical standpoint it is simple and unitary, and we shall henceforth use the term "monochromatic" in this purely physical sense without further qualification. Psychologically, however, sensations evoked by certain "monochromatic" rays often appear to be mixtures of two adjacent colors, such as blue and green; and conversely, a sensation evoked by a mixture of colored lights, such as red and green may appear as a single color, yellow, which from an introspective point of view is absolutely different from the colors that would be evoked by the same stimuli acting separately, and is indistinguishable from the yellow produced by monochromatic light.

The hue of any "monochromatic" light may be perfectly matched by mixing in proper proportions other lights of neighboring wave lengths. Thus, a mixture of red and yellow gives orange. Violets and purples are obtained by mixing red and blue. Some of the purples, psychologically intermediate between red and violet, can be obtained only by color mixture, because there is no monochromatic light which will evoke them. Introspectively these purples appear as simple and unitary as most of the spectral colors, with the exception of pure red, yellow, green, and blue.

Mixing lights of different wave lengths frequently results in a loss of saturation. The less saturated a color becomes, the less noticeable is its hue, until a point is reached at which hues become indistinguishable, and the colors (sometimes called "neutral colors") differ only in brilliance (or luminosity). Maximum luminosity is known as white, minimum as black, and the intermediate shades as grays. Theoretically there should be only one white and one black, but the term white is commonly applied to any of several light grays and the term black to any of several dark grays. Thus a piece of "black" paper may be "blackier" than the blackboard, a piece of "black" velvet "blackier" than either, and none of them as black as the interior

of a dark box seen through a small opening. Likewise, three or four specimens of "white" cloth may differ greatly in "whiteness" and none of them will be as white as snow. The terms "black" and "white" when applied to ordinary objects are terms of convenience rather than precision.

Some authorities, following popular usage, reserve the name color for sensations of definite hue, and refer to black, white, and grays as "colorless lights." White (or gray) can be produced by a mixture in proper proportions of red, blue, and green lights. It can also be produced by mixing red, green, and violet in somewhat different proportions, using less red this time. It can also be produced by mixing any of several pairs of colors, known as complementaries. For every hue there is another hue, its complementary, which when mixed with it in proper proportion will give a neutral color or colorless light. Thus, the complementary of a red of 656 m μ is a blue-green of 492 m μ ; the complementary of an orange of 608 m μ is a blue of 490 m μ ; that of a golden yellow of 574 m μ is a blue of 482 m μ ; that of a greenish yellow of 564 m μ is a violet of 433 m μ . The white lights produced by these mixtures are indistinguishable when equated for brightness.

Most investigators have regarded three or four colors as "primaries," believing all other colors to be mixtures of these. Different sets of so-called "primaries" have been proposed according to the different kinds of facts the investigators had in mind. For example, in the fine arts, the primary colors are often taken to be red, blue, and yellow, because certain paints and inks of these colors can be mixed to obtain all other hues. In physics, on the other hand, the primary colors are sometimes taken to be red, blue, and violet, and sometimes to be red, blue and green, because colored lights of either of these sets of three "primaries" can be combined in such a way as to obtain every other color.

In discussing color mixture, it is necessary to distinguish sharply between additive mixtures (mixtures of colored lights) and subtractive mixtures (mixtures of pigments). Every colored material absorbs light of certain wave lengths and reflects light of other wave lengths and may also transmit light of still other wave lengths. When artists speak of "mixing colors,"

they refer to the mixing of pigments, which consist of small particles of material chosen because of their property of reflecting light of definite wave lengths and absorbing light of other wave lengths. Paints and inks consist of finely divided pigments suspended in oils or other liquids. When paints are mixed, each pigment continues to absorb its own characteristic absorption spectrum, and the light which is finally reflected from the mixture is whatever is left. For example, a blue pigment might absorb all red, yellow, and orange rays, and reflect all the blue and part of the green and violet. A yellow pigment might reflect the red, orange, yellow, and green, but absorb the blue and the violet. Now when these two pigments are mixed, the only color not absorbed by one or the other of them is the green. Hence, the mixture will appear green. Thus, the artist's process of mixing colors is a subtractive one.

The mixtures of physicists and psychologists, on the other hand, are additive ones. There are three or more different methods of attaining such a mixture: (1) by superposing parts of different spectra, (2) by arranging a system of reflectors to transmit light from different sources, or reflected from different colored surfaces, along a common path to the retina, and (3) by rapidly rotating a disk with sectors of different colors. This last method is the simplest and most widely used. Its invention is attributed to Sir Isaac Newton. The retinal impression of each color persists for about 1/30 of a second, and when the disk rotates rapidly enough, the colors appear to blend. By measuring the angles of the different sectors, it is possible to make precise specifications of the amounts in which any group of colors is mixed to match any other color.

Persons who require three spectral colors to match all other colors are known as trichromats. These include all persons of normal vision, and some whose color mixtures differ markedly from the average and who are therefore known as "anomalous trichromats." In 1881 Lord Rayleigh discovered that apparently normal people may require very different amounts of lithium red (670 m μ) and thallium green (527 m μ) to make a mixture matching sodium yellow (589 m μ).

There are many persons (estimated as about 4% of males and .4% of females) who can match all colors by a mixture of two spectral

colors, and are therefore known as dichromats. All color matches made by normal persons are recognized as such by dichromats, but the converse is not true. Hence, dichromats do not possess any variable which normal persons lack but they lack some variable which normal persons possess. Dichromats recognize blue and name it correctly, but they confuse red, green, and yellow.

There is some evidence that dichromatism, or partial color blindness, is hereditary as a sex-linked Mendelian character. (See *heredity*.) Nevertheless, attempts have been made to improve color vision by feeding Vitamin A, particularly after the spectacular success attained in improving night vision and increasing the speed of dark adaptation by feeding Vitamin A. The extent to which this method may be helpful with color vision is still in dispute. H. Cadan (1943) has used a combination of vitamins, tincture of iodine, and electrical stimulation in the attempt to treat color blindness. In 1942, K. Dunlap and R. D. Loken reported success in treating color blindness with Vitamin A. Such treatment sometimes enables a patient to pass a color vision test on which he has previously failed. The permanence of the cure is not known, but even if the continuance of high vitamin feeding were required to maintain visual efficiency it would be well worth while, both from the standpoint of the individual and from that of society. In the same year, J. H. Lepper reported cases of reconditioning the color-blind by practice with visual filters. Obviously these cases could not have been true color blindness in the ordinary sense of the term. E. Murray has pointed out that the old hard-and-fast categories of color blindness are a handicap to understanding individual variation in color deficiency. According to E. G. Boring, the distribution of color sensitivity is not bimodal, as is sometimes supposed. It is probable that the number of trichromats with varying degrees of anomaly in their color vision considerably exceeds the total number of dichromats.

Early discovery of the extent to which color blindness runs in families also led to premature emphasis on hereditary factors and neglect of the possibility that some cases may be dietary rather than hereditary.

Furthermore, premature explanations of color blindness in terms of color theories led to a hasty assumption that blindness to a particular

color at least ought to be an all-or-none phenomenon.

In 1937, Seebeck discovered that two groups of dichromats can be distinguished. One of these has the red end of the spectrum shortened and the region of greatest luminosity shifted toward the green. For the other, the entire spectrum is visible and the relative luminosities of the various wave lengths are approximately the same as for the normal eye.

Partially color-blind persons are often unaware of the extent of their own defect. Guided by shapes, variations in brightness, and objective context, they often call colors of objects by their right names, but are confused as to the colors of lights.

Because of the use of colored lights as signals on highways, railways, and ships, detection of the partially color-blind and their exclusion from occupations in which color confusion might create a hazard is of the utmost practical importance. Railroads require color vision tests for all their engineers. Some states now require a color vision test for an automobile driver's license. Navigating officers, aviators, and officers and personnel in many branches of the armed services require perfect color vision for the adequate performance of their duties.

Many different tests of color vision have been used. One of the oldest is the Holmgren test, in which the subject is required to match colored skeins of wool. It is said that sailors sometimes object to this test on the ground that it is "effeminate." They readily cooperate in a test with colored lanterns, because this appears more practical and more obviously relevant to the duties of their profession. Nevertheless, lantern tests are less reliable in many cases, because differences in brightness of the colored lights provide secondary cues which enable the color-blind subject to name correctly colors which he does not really see. The Board of Trade lantern eliminates this possibility by making all the lights of the same luminosity. The Ishihara test and several others patterned after it make it possible for the examiner to discriminate between genuine color blindness and malingering. The test material is a series of cards with pink and green dots. The different dots vary slightly both in hue and in brightness value; but for the person of normal vision figures formed by pink or reddish dots stand out upon a background dotted with green in the case of

some cards, whereas figures formed by green dots stand out against a pink-dotted background on other cards. But for the dichromat who sees no pink and green totally different figures may be formed in dots of blue and yellow (or brown), because dots of purplish pink and bluish green will both appear blue, whereas dots of yellowish green and pinkish orange will both appear yellow. Therefore color-blind persons can read some figures that are not legible for normal persons and vice versa. Hence when a subject who is not illiterate claims that he cannot read any of the figures on the cards, there is a strong presumption of malingering. Minor anomalies of color vision, too slight to be detected by ordinary tests, can be measured by Nagel's anomaloscope, which employs Lord Rayleigh's method of mixing red and green in measured amounts to match yellow.

There has been much dispute as to what the partially color-blind actually see, and too often their vision has been described *a priori* in terms of one or another of the color theories. Though color defects are usually binocular, several cases of monocular color blindness have been reported in the past 65 years. In these cases of course the subject is able to make direct comparisons between what he can see with the normal eye and what he can see with the defective eye. Such cases are unanimous in reporting that the color-blind eye sees blue and yellow but not red and green nor any of the other hues. Pure greens and reds are seen as yellows, a bluish-green as blue, and a purplish red also as blue. The patterns seen by the partially color-blind in the Ishihara test afford further confirmation of this fact.

These facts of partial color blindness are among the important evidence that yellow ought to be included among the primary colors. Another important item of evidence in favor of yellow is the fact that it can be seen over a wider area of the retina than either red or green.

In normal eyes there are three retinal zones, a central zone, surrounding the macula lutea, in which all colors are perceived in their true hues, an intermediate zone in which no colors are seen except blue and yellow, and an outer zone in which all colors appear as grays. (Some observers, however, report that if colored stimuli are sufficiently intense, they can be seen

in their true colors to the periphery of the retina.) Much experimental work has been done upon the mapping of the zones of the retina. Their size and shape differ noticeably in different eyes. In passing from one zone to another, most colors appear to change in hue. An orange, for example, will appear as a gray shadow in the periphery. In the intermediate zone, it will appear as a dull yellow. Only in the central zone will it be seen as orange. Both reds and greens are seen as yellow in the intermediate zone, though Ferree and Rand have found that red stimuli are recognized as such at a greater distance from the fovea than are green. There is one pair of colors, a bluish red and a bluish green, which disappear abruptly at the edge of the central zone, their stimuli being seen as gray in the intermediate zone. Hering regarded these as "primary" colors, along with blue and yellow. Yellow and blue are distinguished in their true colors over a wider area of the retina than any other hues. This is evidence that both of them are primary colors.

The most conclusive evidence in favor of blue was recently (1944) established by G. F. Göthlin in a series of experiments on the threshold energies for the appearance of color in spectral light of wave lengths varying from 430 to 455 m μ . It will be noted that these wave lengths fall in the range of Listing's ultramarine indigo, a hue beyond the pure blue toward the violet. As the energy of the stimulus was increased from zero, all of Göthlin's observers first named the color as blue, and only when the energy was made several times greater was another component identified. No observer reported the appearance of violet or green before blue. Now if blue were a blend of green and violet (as some physicists still maintain), then we should expect the primary present in greatest abundance, which in this case would be violet, to be visible at a lower energy level than the blue; but the reverse is the case. Hence it seems evident from Göthlin's experiment that blue is the short-wave fundamental color and violet is not a fundamental color but a blend.

Every color tends to induce its complementary upon its immediate surroundings. This phenomenon may be demonstrated by mounting a patch of saturated color upon a neutral gray background and eliminating contours by covering with gauze or thin tissue paper. Under

these circumstances, the gray background will appear tinged with the complementary of the brightly colored patch. By this means, the same piece of gray cardboard can be made to appear bluish, brownish, lavender, pinkish, or bluish-green, according as it is made the background for yellow, blue, green, blue-green, or red. Artists make use of this phenomenon to enhance the apparent saturation of their colors by placing contrasting colors side by side.

When a patch of color is fixated steadily, its saturation gradually diminishes. It is almost as though a gray cloud were forming between the color and the observer. This phenomenon is known as *adaptation*. Adaptation also occurs when one wears colored glasses or remains under colored illumination. When red glasses are first put on, all the world looks red. Soon, a few other colors can be distinguished, but white things still appear to have a reddish tinge. Eventually, however, all objects appear in their true colors. Then, when the red glasses are taken off, everything appears abnormally bright, and white objects have a bluish-green tinge; but in a short time, varying somewhat with different observers, all things resume their normal appearances. Similarly when artificial lights which have an orange hue are first turned on, the orange color is clearly perceptible. In a few minutes, however, the orange has disappeared and practically all objects in the room have their natural colors. If one then looks out of the window into the gathering twilight, objects out of doors appear bluish. In general, whenever one is adapted to illumination of any definite hue, objects illuminated with white light appear tinged with the complementary of that hue.

If after steady fixation of a brightly colored area one closes the eyes or looks away at a neutral background, the complementary of the color is seen. This is called the negative after-image. The negative after-image is of the same general shape as the stimulus, but the outlines are more vague. The size can be made to vary according as one projects the image upon a distant background or a surface near at hand. The farther the image is projected, the greater is its apparent size. Presumably the after-image area on the retina is nearly the same as that occupied by the original stimulus, or slightly larger at first, diminishing as the after-image fades out. If a negative after-image is projected

upon a colored background, its hue blends with the background, following the same laws of color mixture as those established with the color wheel.

The complex interrelationships among colors become more intelligible when the colors are arranged according to some spatial schema. Leonardo da Vinci arranged the colors in a square with red, yellow, green, and blue at the corners, secondary hues along the sides, and tertiary or unsaturated colors inside. Sir Isaac Newton proposed two different spatial arrangements, the circle and the triangle. Spectral hues are arranged around the circumference of the circle with purple bridging the gap between red and violet. Colors of decreasing saturation occupy the space from the circumference inward toward the center, at which is white, or colorless light. The distance of a point from the center is a measure of its saturation. In Newton's color triangle, red, green, and violet are at the corners. Newton's diagrams specify hue and saturation adequately and also indicate which colors can be mixed to form other hues and what proportions are required; but they provide no means of representing the third variable, brilliance or value. Lambert proposed a tridimensional figure. Titchener achieved a geometric representation of all the important facts of color mixture by his double pyramid, with white at the upper apex, black at the lower apex, the complete series of grays on a line joining these apices, the saturated colors around the outer edge of a quadrilateral base, with one of the four primaries (red, blue, green, and yellow) at each corner, and the base so tilted as to take account of the greater brightness of yellow and the relative darkness of red and blue. Dark shades are represented in the lower half of the double pyramid and light tints in the upper half. Decreasing saturation is represented by a closer approach to the center line. Complementaries lie at opposite ends of straight lines passing through this center line.

In dim light, ordinary colors are not seen. All objects appear black or gray. Faint lights appear white, whatever their wave length. There is considerable evidence that the mechanism for night vision, or vision in dim light, is entirely distinct from that of ordinary daylight vision. Night vision is thought to be mediated by the rods of the retina, daylight vision by the cones.

Rods are absent from the fovea and most abundant at the extreme periphery of the retina. Cones are thickest in the fovea, becoming fewer and fewer farther out, and are practically absent from the extreme periphery. For ordinary daylight vision, acuity is greatest at and immediately around the fovea, but the fovea is blind to very dim lights. A dim star which is plainly visible in indirect vision disappears when one looks directly at it.

Night vision is commonly called "twilight vision" because some of the most interesting phenomena connected with it were first observed in the twilight, or period of transition between ordinary daylight vision and night vision. At this time, reds become very much darker, gradually changing to black, and blues become pale and silvery. There is a shift in the brightest part of the spectrum from yellow toward the green. The brightness distribution in night vision is identical with that of the totally color-blind, and with one type of partially color-blind, and with that of the periphery of the normal eye at all times.

The transition from daylight vision to night vision is ordinarily gradual, dark adaptation requiring a varying period of time in different individuals. The frequency of night flying in the Second World War brought problems of night vision and dark adaptation into sudden prominence. Pilots must look alternately at a lighted instrument board and into the outer darkness. Their ability to see in the darkness is of utmost practical importance. Hence there have been many recent research studies concerning various factors related to dark adaptation. M. E. Yarbrough and W. J. Dann have found low but positive correlations between dark adaptometer measurements and blood Vitamin A. The chemical structure of the visual purple, the photosensitive substance in the rods now known to be the substance involved in night vision, is related to that of Vitamin A, and there seems to be some evidence that an increase of Vitamin A in the diet improves the rate of dark adaptation. Other investigators, both in America and in Russia, have studied the relation of dark adaptation to various environmental factors. K. Kekelcheyev, N. Derzhavin, and S. Pilipchuk (1943) find that the sensitivity of the already dark-adapted eye can be improved by short, feeble stimulation of any other receptor. Intense or prolonged stim-

ulation has the opposite effect. W. R. Miles (1943) has found that when red goggles are worn, dark adaptation can proceed in a lighted room. This is of course what we should expect from the fact that the red glass absorbs the green rays, those to which the visual purple is most sensitive. The use of red light instead of white for cockpit illumination also serves to protect the pilot's dark-adapted eyes from the blinding effect of green rays. C. P. Seitz and J. Orlansky (1944) have found that visual sensitivity to dim light is about four times greater after viewing a panel illuminated with red light than with white.

About the mechanism of night vision there is general agreement. Concerning color vision, many different theories have been proposed. The three most widely accepted are (1) the Young-Helmholz Theory, (2) the Hering Theory, and (3) the Ladd-Franklin Theory.

Counting physicists, engineers, physiologists, medical men, and psychologists, the Young-Helmholz Theory with its various minor modifications has probably had more adherents than all the other color theories combined. It postulates three fundamental color processes, red, green, and blue (or violet), because all other colors can be matched by mixtures of these. Unfortunately, this theory fails to account for some of the other facts of color vision. For example, it fails to explain why yellow should be visible farther out toward the periphery of the retina than red and green. If yellow were simply a mixture of red and green, it should disappear when they do. Also, it fails to explain why yellow is seen by partially color-blind eyes that cannot distinguish red from green. This fact has been established by the testimony of several persons who were partially color-blind in one eye and could see all colors with the other.

The Hering theory postulates three photochemical substances in the retina, the black-white, the blue-yellow, and the red-green, and assumes that each of these is responsible for two opposite sensations, depending upon whether it is being broken down or built up. According to this theory, when the black-white substance is being built up, a sensation of white or brightness occurs. Every kind of visible light tends to break down the black-white substance to some extent. Hence every colored light has a white component. When the black-white sub-

stance is being built up, a sensation of black results. Yellow light breaks down the blue-yellow substance and in so doing produces a sensation of yellow. Blue light causes the blue-yellow substance to be built up, and this leads to a sensation of blue. Red light disintegrates the red-green substance and green light builds it up. The various intermediate color sensations are due to simultaneous changes occurring in the three different color substances. Thus a blue-green light would break down the black-white substance but build up the other two. A yellow-green light would break down the black-white substance and the blue-yellow substance but would build up the red-green substance. A lavender light or violet light would break down the red-green substance as well as the black-white but would build up the blue-yellow.

The Hering theory further presupposes that even when the eyes are closed, these photosensitive substances are continually undergoing metabolic changes, some molecules being broken down and fresh ones being built up, but that the two processes balance each other, maintaining a state of equilibrium. Now when an external stimulus acts upon them, the equilibrium is upset in one direction or the other, but whenever this happens, an opposing tendency is set up, to restore the equilibrium. For example, if red light falls upon some part of the retina, causing the red-green substance there to be broken down, immediately there is a tendency for rebuilding, resulting in a decrease of the apparent saturation of the red seen. Now, if the subject closes the eyes, the rebuilding of the red-green substance continues, resulting in a sensation of green over the area previously occupied by the red (negative after-image). If a photochemical substance has been built up beyond the normal equilibrium point (as by the action of green light or blue light), then there is a tendency for it to disintegrate spontaneously for a time until the equilibrium point is reached. On the basis of these assumptions, it is possible to account for all the observed phenomena of after-images and adaptation.

The Hering Theory explains partial color blindness on the assumption that the partially color-blind lack the red-green substance. It accounts for retinal zones by assuming that only the black-white substance is distributed throughout the retina, and that the blue-yellow sub-

stance is more widely distributed than the red-green.

One criticism of the Hering Theory is that it assumes that red and green are complementaries. Pure red and pure green are not complementary, but form yellow when mixed. The attempt to get around this difficulty by choosing as "primaries" a bluish red and a bluish green which are actually complementary resulted in forfeiting one of the main advantages of the theory, namely, that its primary hues are those of introspection and common sense.

Because the Hering theory conceives of black and white as antagonistic processes, tending to cancel each other out, this theory has difficulty in accounting for neutral gray. G. E. Müller sought to account for neutral gray by ascribing it to the activity of cells in the cerebral cortex. Hence it is often called "cortical gray." The difficulty with this view is that neutral gray appears very little different from the light grays just above it or the dark grays just below. If its origin is so utterly different, it is hard to conceive how its appearance could be so nearly identical.

The Ladd-Franklin Theory postulates a photochemical substance in the rods and cones which is decomposed by light, giving off different cleavage products in response to radiations of different wave lengths. It assumes that these cleavage products stimulate different nerve endings in the retina, thus setting up nervous impulses which ultimately result in sensations of color. This photochemical substance is thought to have gone through three stages of evolution, each of which is still represented in some part of the normal human eye. At the periphery of the eye, we find the most primitive stage, in which a single big cleavage product is given off in response to any visible light. This product (designated as W) results in a sensation of white or colorless light. Some lower animals have eyes in this stage of development. Somewhat nearer the center of the normal eye is a zone sensitive to blue and yellow. Here the photosensitive substance in the cones is thought to yield two cleavage products, B in response to short waves, giving a sensation of blue, and Y in response to long waves, giving a sensation of yellow. It can be shown experimentally that pure reds and greens falling upon this part of the retina are seen as yellow. A purplish red or a bluish green, on the other

hand, appears in this zone as colorless. This is explained by assuming that when Y and B are both split off they unite chemically to form W, which stimulates the nerve endings for the sensation of white. The complementarity of yellow and blue is explained on the same hypothesis. In the innermost zone, surrounding the fovea, all colors are seen. Here, the Ladd-Franklin theory assumes, the photosensitive substance of the fully developed cones gives off three cleavage products, R for the longest waves, producing a sensation of red, B for the shortest, producing a sensation of blue, and G for those near the middle of the spectrum, producing a sensation of green. When R and G are split off simultaneously, they unite chemically to form Y, giving rise to a sensation of yellow, just as Y and B unite to form W, giving a sensation of white. On the basis of these assumptions, it is possible to account for all the facts of color mixture and complementaries. After-images can be accounted for on the assumption that after a molecule has once started to disintegrate it breaks down completely, giving off those cleavage products not given off at first.

According to the Ladd-Franklin theory, color-blind eyes are atavistic, representing a more primitive stage of evolution. The totally color-blind, who are very rare, represent the earliest stage, in which all visible things appeared white or gray. The dichromats, who are relatively common, represent the stage in which the photosensitive substance yields two cleavage products, B and Y.

The Ladd-Franklin theory interprets black as a sensation arising when no light reaches the corresponding part of the retina at a time when other retinal areas are receiving stimulation.

Each of these color theories and various others that have been proposed from time to time succeeds in accounting for some of the principal facts of color vision but leaves other well-established facts unexplained. Each of them, especially the Helmholtz theory, has inspired much painstaking research; and each by becoming a thesis to be defended has made its most ardent advocates somewhat resistant to new facts not in accord with the favored theory. Here, as in other areas of science, it is perhaps best to take the attitude of multiple hypotheses, recognizing that the facts are not yet all dis-

covered, particularly the biochemical facts, on which the final acceptance of any one of the theories must depend.

CONCEPT FORMATION.—Concept formation is the process whereby an organism develops a symbolic response—usually, but not necessarily, linguistic—which is made to the members of a class of stimulus patterns, or to an aspect of such a class, but not to other stimuli. When such a generalized symbolic response represents the members of a class of stimulus patterns the organism has formed a class concept (for example, “chair”). When such a response represents an aspect of a class of stimulus patterns the organism has formed an abstract concept (for example, “justice”).

Prior to the present century the approach to problems concerning concepts was almost entirely speculative. The philosophers of ancient Greece were deeply interested in the nature of the thing-in-general (the universal, as they called it) and its relations to things-in-particular. Plato held that universals are the original, eternal archetypes of things and that they are realities that are prior to and independent of particulars. Aristotle taught that universals, although not prior to particular things, are realities *in* particular things and that they are more fundamental than particular things. The Stoics and the Epicureans, on the other hand, held that universals are subjective abstractions and that only things-in-particular have real existence.

This ancient controversy continued to find expression in many of the disputes so characteristic of the scholastic philosophers of the middle ages. The question whether universals are real, independent substances was regarded as a matter of great importance by the schoolmen. During the period from the ninth through the thirteenth centuries most of them maintained that an affirmative answer to this question is an essential support of Church doctrine and the philosophical foundation of the Church's intellectual and ecclesiastical structure. During the fourteenth century, however, this view was quite generally discarded even by the most devout schoolmen, and universals came to be regarded not as the essences of things but as “concepts in the mind.”

The sixteenth century witnessed a decline of interest in the question as to whether universals are independent substances and an increase of interest in the question as to the sort of material of which concepts are made. Some philosophers concluded that they consist of psychic stuff,

some held that they are purely physical, and others advanced a variety of other theories. The coming of the doctrine of biological evolution and the rise of experimental psychology in the nineteenth century brought a shift in emphasis whereby concepts were increasingly regarded as complex modes of adjustment. Since that time metaphysical questions concerning the ultimate nature and status of concepts have been, in part at least, superseded by an envisagement of concepts in psychological terms.

The rise of the tendency to substitute psychological investigation for metaphysical speculation did not, however, eliminate differences of interpretation of concepts and concept formation. The “schools” of psychology that have been so characteristic a feature of the growth of the young science have by no means agreed in their interpretations. Some psychologists have thought of a concept as a mere group of reflexes which are characterized by a functional consolidation of neural elements. Others have regarded it as “an image functioning in such a way as to suggest a definite meaning, or core of meanings, which the mind attaches equally to all the individuals of a group, or species” (Miller, 12, 192). Many other widely-differing views have been advanced. These differences among psychologists have probably been as great as those among philosophers, but the theories propounded by the psychologists have enjoyed the enormous advantages of being accompanied by, and of being the stimulus for, experimental research.

Psychological experimentation during the nineteenth century was largely concerned with relatively simple processes. Making its appearance at a time when the scientific world was deeply stirred by the idea that complex things and events grow out of relatively simple things and events, experimental psychology quite naturally turned first to problems of a relatively simple character. Since the turn of the present century, however, experimental studies have been made of complex processes such as concept formation, and in recent years a considerable degree of interest along these lines has developed.

A central problem of the earliest experiments on concept formation was that of determining whether there are any images that are generic, i.e., whether an image can stand for a whole

class of objects. Watt (26) and Messer (11) of the Würzburg school conducted investigations that seemed to establish the reality of such images, a conclusion later confirmed by Stevanovic (24). Verbal generalization was employed in the experiments by Watt and Messer; the subject was given a pair of words for which he was asked to state a superordinate. A subsequent study by Gelb and Goldstein (6) showed that generic images do not differ from particular images in clarity or brilliance; the only difference is that generic images are treated as representing classes of objects rather than individual objects.

The study of imagery was also an important part of an early experimental study of concept formation by Fisher (5), an American psychologist who made a thorough investigation of certain aspects of the problem from the point of view of structuralism. Using visual material and an introspective technique, she concluded, among other things, that imagery of both general and particular features of her geometrical nonsense figures tended to become more vague, more attenuated, and less colorful as repetition increased. She also confirmed the result reported by Külpe (10) that in situations wherein abstraction is possible visual features which the subject is not motivated to perceive tend to drop out of experience.

More recent investigations have dealt with a wide variety of problems. The question of the means whereby concepts are formed has received the attention of a number of research workers, practically all of whom hold that analysis of the learning material and grouping are basic to the process. Ach (1) states, first, that under the influence of the determining tendency similars are grouped with similars; second, that the groups are handled by an "idea" that makes possible an economical solution of the task; and third, that in this process differences among the members of the group tend to be averaged out. That trial and error play an important part is generally recognized. The process of concept formation is not necessarily a gradual one, however; at times the learner may manifest insightful behavior and acquire the concept quickly (Smoke, 23). The entire process may be, and frequently is, quite unintentional. Both induction and deduction are usually involved. Manipulation of the object may play an important part (Berkenblit, 2).

Enormous individual differences occur (Humphrey, 9).

Stimulated by the work of Piaget (15, 16, 17), many studies have been made of the growth of concept formation in children. Four general stages may be recognized in the development of a concept in a child. The first stage is presymbolic, and consists in the fact that the child has learned to react in characteristic ways to a particular object. In the next stage the child employs a symbol, usually a word, that stands for the particular object in question but not for a class of objects. In the third stage the child is capable of implicit responses that are symbolic of the class in question, but he is unable to give a satisfactory verbal formulation of the concept. The final stage is evidenced by the child's ability to give an acceptable definition. An integral part of this development is the growth of the child's ability to organize objects in groups. Werner (28, 238-240) reports that up to the age of four most children group objects in terms of only one characteristic, usually color or form. A somewhat higher level of development is reached when the child can be shown that the remaining characteristics can be the basis of the creation of sub-groups. Still later he may make these divisions unaided. Finally, like a normal adult, he may be able to preview his task as a whole and implicitly organize objects into groups in terms of a number of characteristics.

Sometimes a concept is formed from a group of stimulus patterns all of which are positive instances, i.e., members of the class in question. Much of the time, however, concept formation proceeds on the basis of stimulus patterns some of which are positive instances and some of which are negative instances, i.e., not members of the class in question. Studies of the effects of these negative instances show that although they "may not make for rapidity in learning they tend to make for accuracy, especially in the case of difficult concepts. It appears that in so far as negative instances assist concept learning they do so largely because of the way in which they prevent the learner from coming to one or more erroneous conclusions while he is still in the midst of the learning process" (Smoke, 22, 588).

Subjects in experiments are frequently able to demonstrate the fact they have formed a given concept by going through a test series

faultlessly, and yet be quite unable to give an accurate verbal formulation of the concept (23). This is true of relatively simple concepts as well as more complex ones. (It is of course recognized that there are some concepts that cannot be defined with exactitude, and that concepts are never static or absolutely complete and final.)

Additional problems typical of those that have been investigated in recent years are these: the relation between a child's concepts as revealed in his drawings and his personality traits (Mout, 13); the hierarchical development of concepts (Welch, 27); the use of tests of concept formation as diagnostic aids in clinical work (Reichard and Rapaport, 18); the formulation of a set of norms for the evaluation of the degree and type of impairment in clinical cases (Reichard, Schneider, and Rapaport, 19); the extent to which children can form the concept of middleteness without being given verbal cues (Graham, Jackson, Long, and Welch, 7); and the use of Ach's technique, as modified by Sakharov (20), in the study of psychotic patients (Vigotsky, 25).

A number of points of view have been basic to experimentation on concept formation during the past twenty-five years. One of these holds that concept formation consists in finding a "common element" in a group of stimuli. This view has been widely held and has constituted the theoretical basis of numerous experiments. Hull (8) in a well-known investigation regards his subjects as having "evolved" a concept when they discover the "common element" hidden in each member of a group of Chinese characters. Each character in a given group has this "common element" in the sense that it contains "certain strokes in common" with the other characters in its group, and the process of finding these "common elements" is taken to be "the evolution of concepts." Moreover, Hull and others indicate that the "common element" is the concept so far as they are concerned.

This way of viewing concept formation has been criticized by the present writer (23, 2-5) as being an over-simplification in that it deals not with the entire process of concept formation but only with that aspect of it commonly known as abstraction. The processes whereby a young child forms the concept "dog" (Hull's example) are not merely those of locating an

identical "common element" in a group of stimuli. If there are any elements present they are not evolved by the child, for elements are never evolved—they are merely analyzed out. As the child learns more and more about dogs, his concept of "dog" becomes richer, not a closer approximation to some bare "common element." Concept formation involves synthesis as well as analysis.

The process of discriminating a type of form has been regarded as concept formation. Thus, Fields maintains that white rats can develop the concept of triangularity. He writes, "the specific acquired reaction involved in the 'jump to triangle' of the rat will be considered as equivalent to the child's specific language response 'triangle.'" (4, 4). The present writer regards this as another instance of over-simplification. The child's language response "triangle" is symbolic of a class of stimulus patterns, whereas the white rat, although capable of certain types of discrimination and certain generalized habits, gives no evidence of being capable of any comparable symbolic response.

The process of discovering a principle or rule has been regarded as concept formation. Ewert and Lambert (3) state that they were studying concept formation when they investigated the process of discovering a principle for the solution of a problem involving the transfer of discs from one circle to another by way of a third. Similarly, Murphy calls an experiment in which the subject attempts to discover a rule "an experiment on the formation of concepts" (14, 368). The present writer regards concepts as indispensable constituents of principles and rules but holds that the identification of concepts with principles and rules is unwarranted and confusing.

The view of concept formation given at the beginning of this article has been the basis of a series of experiments (22, 23). According to this interpretation the *sine qua non* of concept formation is response to relationships present in each member of a group of stimulus patterns, the stimulus patterns in question being classified as a group by virtue of the fact that they have these relationships, and perhaps certain characteristics, in common. Abstract concepts such as a "justice," "freedom," "integrity," etc., are formed from stimulus patterns that may have only relationships, and one or more aspects of such relationships, in common. Class

concepts such as "chair," "the Stars and Stripes," "mountain," etc., are formed from stimulus patterns that may have not only relationships but also such characteristics as color and size in common. This view of concept formation can be regarded as a point of view for the purposes of experimentation that avoids both metaphysical speculation and commitment to the tenets of any psychological "school."

"The experimental psychologist must have a standard in terms of which he can judge whether his subject has learned a concept. Present knowledge does not make possible the setting up of a biophysical criterion of concept learning, that is to say, it is at present impossible to indicate the neuromuscular and the neuroglandular events that must occur before an individual may be said to have learned a concept. It is entirely possible, however, to set up a biosocial criterion. We propose the following: consistency of differential, generalized, symbolic response" (Smoke, 21, 277, 278). The standard by which one can judge whether a given individual has formed a given concept is this: the consistency with which he is able to make symbolic responses that differentiate the members of the class of stimulus patterns in question, or an aspect of that class, from other stimuli.

CONDITIONED RESPONSE, THE.—Few phrases occur more often in recent psychological writing than "conditioned reflex" and "conditioned response." It is no accident that these were given their vogue by a physi-

ologist. The actual meaning of the phrases was old and familiar. That new stimuli could evoke a response merely because of association with that response was recognized by Aristotle, Descartes, Hobbes, Hume, Locke, Berkley,—in fact by practically all writers who dealt with human behavior and conduct. Common sense and popular proverbs have always recognized conditioning.

The reason it took a physiologist to give new life to the notion of association was that association had acquired too many dubious alliances with theological and physiological notions. Most of the literature of association referred to it as "the association of ideas," although it is clear from the illustrations used by the authors mentioned above that they meant to include associative responses as well as associated thoughts.

Only a physiologist who had no concern with the history of the soul or the relation of body to mind or the nature of human will could have given the concept of association so completely fresh a start. The Russian physiologist, Ivan Pavlov, to whom we owe this fresh interest in associative learning, was a student of the physiology of digestion and the digestive secretions. He had been recording the activity of salivary and gastric glands and investigating the occasions for their secretion. At first the intrusion into his results of what appeared to be something psychic rather than physical was only an annoying complication. When his dogs gave signs of responding to irrelevant stimuli like the sight of the experimenter or an adventitious noise simply because this had been associated with the proper physiological cue of food, this confused the situation. He at first referred to the phenomenon as psychic secretion and thought of it in terms of the association of ideas. The sight of food arouses certain ideas of food. Those ideas have been associated with ideas of eating, and ideas of eating have a mysterious "ideo-motor" effect which accounts for the reappearance of the chain of causation as a physical event.

Not being concerned with the mind-body problem, Pavlov searched for the conditions under which this "psychic" secretion appeared. Influenced by the traditional notions of the association of ideas, he found those conditions in the association between the new signal (e.g., bell) and the original stimulus (food), which

latter was presumably the inborn or inherited stimulus for reflex secretion. The psychic secretion appeared to be conditional on an association with the original stimulus. The first English translations of his work established the word "conditioned" and "unconditioned" instead of "conditional" and "unconditional," which would have been more exact translations of the Russian phrases Pavlov used to indicate the new and old stimuli.

Pavlov thought in terms of the physiology of the brain and interprets all of his studies in terms of suppositious brain events. In line with this interpretation, he assumed that the association on which the conditioned reflex obviously depended was an association between certain events in the brain cortex, namely the cortical changes which were the immediate result of sensory impulses from the new and old stimuli. For "ideas" Pavlov had substituted "cortical changes."

This assumption that it is two cortical events occasioned by a new and old stimulus that are associated guided Pavlov's work and has fixed the methods used by the overwhelming majority of psychologists who have worked in the field of the conditioned reflex. In the traditional experiment on conditioning it is these two stimuli that are recorded together with the response used to measure the effect.

Pavlov reported the "psychic secretion" of digestive glands in his book, *The Work of the Digestive Glands*, published in Russian in 1897. This work was brought out in English translation in 1902. In his *Conditioned Reflexes* published by the Oxford University Press in 1927, Pavlov reported a mass of experimental results from work in his own laboratory and the laboratories of his followers.

In a typical experiment the duct of one of the salivary glands is led by a slight operation to discharge to an outer surface of a dog's cheek. The dog is then accustomed to standing in a harness which holds it in place with some freedom of movement, and an apparatus is attached which records the flow of saliva from the duct. Food or acid are used as unconditioned stimuli for glandular secretion. Indifferent stimuli, such as a bell or a touch, which at first do not cause any activity in the gland, are associated with the presentation of food or acid, usually being applied a few seconds before the original stimulus. After a number of pair-

ings of the unconditioned and conditioned stimuli, the conditioned stimuli are found to elicit a flow of saliva in the absence of the original stimuli. Pavlov and his disciples devoted a whole generation of laboratory work to the investigation of the conditions under which a conditioned flow of saliva was elicited or altered.

Outstanding among the generalizations at which Pavlov and his students arrived are the following:

1. Optimum conditioning: (Maximum certainty or strength and minimum practice) occurs when the new signal is given up to five seconds before the unconditioned stimulus.

2. Delayed conditioning: When the conditioned stimulus is begun several seconds or minutes before the unconditioned stimulus, the conditioned response tends to exhibit a corresponding delay after the onset of the signal.

3. Interval between the end of the signal and the onset of the unconditioned stimulus results in a corresponding latent period between the signal and response.

4. No evidence for backward conditioning was found. (This result has been put in question by a number of experiments in other laboratories.)

5. External inhibition: Stimuli other than the signal and the unconditioned stimulus may inhibit the response.

6. Internal inhibition: If the signal is repeated at sufficiently short intervals without the reinforcement of the original stimulus, the response tends to show a decrement. (Later research has established many exceptions to this rule.) From this experimental extinction there is spontaneous recovery. Recovery may also follow interruption by a new, irrelevant stimulus.

7. Internal inhibition: Stimuli which have been repeated without reinforcement tend to become inhibitors of the response.

8. After the establishment of a conditioned stimulus, other stimuli may be found to elicit the response. This was called generalization. Continued practice narrows the range of stimuli which elicit the response to the stimuli which are reinforced in practice. These effects Pavlov interpreted as due to the spread of an excitatory state in the cortex from the projection center of the practiced conditioned stimulus, and, with continued practice, the spread of a corresponding inhibitory state from the same region.

The work of Pavlov has been the inspiration for numerous experiments in Russia, Great Britain, and the United States. The concept of conditioning was promptly welcomed by the American behaviorists with Watson as an example. In the consequent American studies Pavlov's generalizations were adopted in general without change. The time relations between conditioned and unconditioned stimuli were regarded as the critical object of observation and record and few experiments record stimuli other than these or attempted to examine the stimuli accompanying the response. Pavlov's categories of "reinforcement," "internal inhibition," "generalization," "delayed conditioning," were made the subject of investigation.

In applying the concept of conditioning to the problem of learning and habit certain difficulties were encountered. Learning had been studied mainly through the device of the problem box and the maze, situations in which the items of record were time, errors, and goal achievement. A definition of learning in terms of achievement has dominated American and British studies. Learning is defined in terms of improvement in the accomplishment of some end goal,—not as Pavlov conceived it in terms of altered behavior, without reference to purpose or satisfaction.

Since the chief use of theories of learning lies in discovering how best to improve behavior, to acquire skills in effecting results, to economize time and effort in necessary tasks or goal activities, there is a consequent tendency to define learning in terms of achievement and attainment and to disregard behavior changes that are not improving. These are either disregarded or dismissed. By some psychologists Pavlovian conditioning is assumed to account for the acquisition of bad habits or wasteful modes of behavior, while other forms of learning are used to explain success and improvement.

A number of psychologists have attempted to unite the notion of simple associative response or conditioned response, which is formulated without mention of improvement, with the observed generalizations about improvement and goal achievement.

This is done by Hull through a modification of the Pavlovian notion of reinforcement. Pavlov used this merely to indicate trials in which the unconditioned stimulus is repeated, thus

guaranteeing the occurrence of the response. In Hull's terminology, reinforcement is something quite different. It is anything which happens to the animal after the response which serves in some way or other to establish or strengthen the associative connection between conditioned stimulus and conditioned response. With Pavlov it was the mere association between new stimulus and old that was effective in connecting the new stimulus with the response. With Hull and numerous other American writers it is not the fact of association, but a later condition of "reward," "confirmation," or "reinforcement" that operates to make the connection. Using reinforcement as his basic idea rather than association, Hull has formulated by far the most extensive and consistent theory of learning thus far offered, and many of his students have been occupied in laboratory experimentation to test the generalizations consequent to his theory.

Miller and Konorski (1928) and later Skinner (1935) advocate distinguishing two distinct kinds of conditioning, classical conditioning illustrated by the Pavlovian experiment and instrumental conditioning, in which the conditioned effect is related to the outcome of the activity and depends on escape or reward. The distinction is based on the nature of the experiment rather than on the nature of the event. Experiments in instrumental conditioning do not observe or record what the animal was doing when the new signal is presented, which is the basic situation in association.

E. C. Tolman in his *Purposive Behavior in Animals and in Man* has attempted to reconcile the facts that animals and man do achieve goals and improve performance with the notion of association, by suggesting that the items associated are not two stimuli, or a stimulus and a response, but meanings. The bell becomes a signal, not for direct secretion of the salivary gland, but for the desirable end-result of being fed. The bell becomes a signal of food. Or it may become the sign of an injury to come and thus lead to avoidance. Tolman's theory leaves the animal to its own devices as to what to do about these signs of coming good or bad fortune. Elmer Culler, like Tolman, holds that the conditioned stimulus becomes not a signal for the response associated with it, but a signal for anticipating the outcome by performing some appropriate movement. Just what that

movement will be is not indicated by this theory.

Pavlov himself has made little application of his generalizations concerning the conditioned reflex to human or animal behavior. He thought of his experiments as an attack on the problem of brain physiology. Bechterev, a Russian, published in 1913 his *Objective Psychology* in which the conditioned reflex was made the basis of a whole system of psychology, which he later called Reflexology. In the United States, John B. Watson (1911) and later Stevenson Smith and E. R. Guthrie (1919) used conditioning as the basic principle of theories of learning. Clark Hull, as mentioned above, uses a modification of the notion of conditioning depending on what he calls "reinforcement," as the central postulate of his systematic theory of learning. Numerous writers accept the phenomenon of conditioning as described but believe it to be only an occasional and subordinate phenomenon sometimes occurring in behavior, not as a fundamental description of all learning. Among these are Wolfgang Kohler (1929), E. C. Tolman (1932), and Raymond Wheeler (1929).

An excellent account of current issues in the theory of conditioning is Kenneth W. Spence's chapter on theoretical interpretations of learning published in Moss's *Comparative Psychology*, revised edition, New York, 1942.

COUNSELING IN STUDENT PERSONNEL WORK.—Although composed of services long performed for the benefit of students, student personnel work is a relatively recent addition to the administration of colleges and universities. It consists largely of those functions usually covered by the terms "admissions," "testing," "counseling," "remediation," "mental hygiene," "health," "financial aid," "discipline" and "student activities." The administrative structure of these functions differs materially from college to college. In some cases, two parallel structures, one for men and one for women, have for many decades presented special problems of coordination. In all colleges, the problems of correlating all functions have presented serious administrative difficulties. Despite these difficulties, however, every college provides at least some rudiment, however inadequate, of all these services for contemporary students.

Restriction in space precludes more than mention of these services. One service, namely, counseling, is one of the basic functions for all students. Other fundamental functions, such as group work, cannot be discussed here. Counseling is chosen for extended discussion because of the current emphasis upon programs which assist the individual to gain insight, orientation and control of his adjustments. Counseling is that phase of student personnel work wherein the student and the counselor together seek to reorder the student's life in such a way as to maximize his adjustments and minimize his maladjustments.

HISTORICAL DEVELOPMENT

Counseling procedures have developed, during the past few decades, out of the current philosophy of individualized education. Through the application of statistical methods and research in various aspects of individual differences, it has become possible to use psy-

chological knowledge and techniques in helping individuals, as opposed to classes and groups, in their personal adjustments and intellectual growth.

In 1909, Parsons proposed a methodology of assisting individuals to select a vocation. Modern techniques of counseling have progressed far from that early beginning and now utilize techniques developed in the Army personnel program during the first world war, and in business and industry during subsequent years. Today counseling techniques draw heavily upon the contributions of psychology in the areas of learning, motivation, emotion, tests and measurements, adolescence, personality and social psychology and also from the fields of education, sociology, mental hygiene, recreation, finance, speech, group work and social case work. Counseling utilizes the knowledge in these areas to bring all available resources to bear upon the adjustment problems of the individual.

In the development of counseling, emphasis originally was placed largely upon the choice of a vocational goal. This emphasis arose chiefly from the concern of students in problems of preparation for their life-work. It was to be expected, therefore, that research in the diagnostic techniques for the measurement of interests and aptitudes progressed more rapidly in these areas than in problems of the measurement of non-vocational interests, social attitudes and other outcomes of general as opposed to vocational and professional education. That problems in the areas of education and vocations were the first to come under a systematic analysis by research methods appears to be largely a result of the sources from which counseling originated—education, the Army, business and industry—and the dominant elements in the philosophy of higher education current in public universities. Profound shifts from this early preoccupation with problems of vocational choice and adjustment are already influencing the counseling movement in colleges and universities.

THE STRUCTURE AND CONTENT OF THE COUNSELING PROCESS

Counseling may be schematically outlined in the following major steps: *analysis* or collecting adequate and relevant data about the student; *synthesis* or summarizing data to high-

light the significant facts and meanings of facts involved in the student's adjustments; *diagnosis* or identifying the "causes" of the student's adjustment problems; *prognosis* or predicting the future development of the adjustment and the outcomes of counseling; *counseling or therapy* or the cooperation of counselor and student to resolve problems and to turn the problem situations into adequate adjustments; and *follow-up* or the determination of outcomes of counseling, the adequacy of subsequent adjustment and the nature and results of subsequent developments experienced by the student.

ANALYSIS

In the making of an individual analysis of a student's adjustment problems, the counselor utilizes the case study. In counseling, the case study consists of procedures used in *collecting*, *recording*, and *analyzing* significant and relevant information about an individual. It includes data reported from associates, tests and other measuring devices and interviews.

Reports from faculty members, parents and others associated with the student and concerned with the detailed facts about and evaluations of his adjustments are collected in various ways. One of the more reliable methods of obtaining such information is that of anecdotal reports. The counselor usually integrates and cross-checks such information to eliminate bias or to discover whether the person reporting has adequate opportunity to observe the student in situations relevant to the adjustment problems being studied or analyzed.

A most important tool in the analyzing of students in the case study is the *psychological test*. There is a vast amount of literature about tests, and a counselor is expected to be well-grounded in the research literature about the major measuring instruments. A test is usually chosen for use in counseling students on the bases of the purpose for which it was constructed, the suitability of the norm group in relation to the student client being counseled and its standardization and reliability. It is desirable that colleges establish local test norms because of the wide variation among colleges in terms of the distribution of the scores of student populations. For example, research on the use of the American Council on Education Psychological Examination has demonstrated

that the median raw scores of student populations can be arranged in an hierarchial order and that there will also be little if any overlapping between the distributions of students' scores in colleges at opposite extremes of the hierarchy. While national norms may be useful in identifying the relative position of a college population, it is more important in counseling individual students for each college to use its own typical norms which are revised periodically.

Adequate tests are available for the measurement of scholastic aptitude and scholastic achievement in the various subject-matter fields, a limited number of aptitudes, certain personality dimensions and a few of the many observed attitudes. Personality tests at present do not have as high reliability and validity coefficients as have tests of achievement. In the use of personality tests, counselors *sometimes* find it valuable to inspect responses to individual items for additional information about the student's adjustment.

Some useful information about individuals may be gained from use of other analytical methods. *Self-ratings* and reports usually consist of personality inventories, autobiographies, personal history and time-distribution records. While such data require objective verification by the counselor from other sources, they are none-the-less real insofar as they reflect the psychological self-orientation of the student regardless of the objective reality of the reported data. A comparison of the subjective report derived through inventory or autobiography, with the objective reality of a stated fact about the student may illuminate the case in such a way that the counselor's orientation—or even his function—may change radically. This is especially true if the student is psychotic or psychopathic. Hence the necessity for verifying the student's report about himself by means of observations and reports from other sources.

Another important, perhaps the most important, technique useful in the case study of an individual is the *personal interview* between the student and the counselor. The interview has been described as having three different functions in counseling: research, diagnosis and treatment or therapy. Although much research remains to be done on the processes and dynamics of the inter-personal relationships in the counseling interview, there is nevertheless

a substantial amount of experimental and experiential literature for use in training the counselor.

Since it is generally agreed that an effective counseling relation cannot be achieved without *rapport*, the interviewer first attempts to put the student at ease and to create an atmosphere which instills confidence and relaxation in the student so that he can discuss his problems without emotional blockings and with the casualness and confidence existing in a conference between two friends of mutual trust. The counselor notes carefully the leads and the meanings, both implicit and explicit, in the verbalization, gestures and inflections of the client. The student's expressive movements are carefully observed because they may provide cues by means of which the counselor may judge other reactions. Furthermore, these cues may indicate reactions which are out of proportion to the problem under discussion and, therefore, stimulate the clinician to look beyond the situation of immediate adjustment to more basic mechanisms involved in the individual's adjustments.

Expressions of surprise or moral judgment by the counselor, in response to statements made by the students, have been found to be not only ineffective but also damaging to *rapport* and therapy. Students would probably not need counseling services if such moralizing or disapproval had been effective as used by non-counselors upon previous occasions. Such responses may be particularly devastating to counseling if the client has emotional problems related to parental, disciplinary or religious conflicts. A counselor, therefore, should accept the individual student with his attitudes and beliefs, spoken or implied. Any attempt to change these characteristics of the student must be skillful and subtle; they require willing cooperation from the student.

The *structuring of the counseling interview* varies with the student and with the nature of the adjustment problem. Often the student is allowed to structure the situation and in such cases further developments depend upon the direction taken, the type of treatment necessary and the most effective and economical means involved in achieving the student's goal. The basis for this conclusion may be found in research which indicates that more ideas are expressed, and expressed more adequately, if

the subject is permitted to tell his story freely and later questioned by the counselor to fill in any gaps in details. Studies in the form of questions best used in interviewing show that the implicative (or leading) is the most unsafe form to use. The question which uses neither a negative nor a definite article is apparently the most reliable.

The interviewer occasionally checks his judgments to see whether the "halo effect" is operating in his *judgments* about the student's personal qualities. This and other forms of bias have been shown to operate so effectively as to secure diametrically opposite results when bias is not controlled in judgment-making by the counselor. Since investigations have shown that half of the reasons given for a judgment of a personality trait were found to be non-specific, the interviewer should constantly guard against making judgments if he has no clear understanding of the factors associated with his judgments.

With respect to the student in the interview situation, the counselor should, upon appropriate occasions, skillfully guide him to observance of the main purposes of the interview, except in such instances as certain types of emotional therapy wherein free association may be desirable. There are other ways in which the student can contribute to confusion or to dispersion of effort, as, for instance, by observing expressions of the counselor with consequent modifications of his behavior in accordance with his interpretation of the counselor's meanings. This may be particularly important to counseling when the student is upset or unstable and when he is seeking a state of dependency.

Since the most common errors of memory have been found to be those of omission rather than those of accuracy, the student's story given in the interview requires further elaboration through questioning and often through verifications from outside sources. Experience reveals that excitement and affective tone tend to improve observation and memory somewhat but, if they are excessive, the reverse occurs. In the interview the counselor faces not only the problem of understanding the student and guiding the interviewing process effectively but also that of evaluating the reports obtained from the student. Interviewing is most likely to be useful in securing information not obtainable from other more objective sources.

SYNTHESIS

In this next step in counseling, the student and the counselor summarize the data already collected. At this point, the data identify the student as an individual differing from others in potentialities, aptitudes, disabilities, hopes, fears and other characteristics. An example of synthesis of objective case data is found in the psychological test profile which summarizes and highlights the salient facts about the student's measured knowledge, aptitudes, interests and personality traits.

DIAGNOSIS

After examining all the data for accuracy, completeness and relevancy, the student and the counselor may formulate an hypothesis concerning the problem of the student. Both may make revisions of this hypothesis as the counseling proceeds. The manner in which assets and liabilities function in the dynamics of life adjustment serves to orient the student and the counselor so that the diagnosis is not oversimplified and so that the counselor may predict future behavior and, in cooperation with the student, determine treatment procedures. In both diagnosis and treatment, the clinician may use not only objective data but also insight, subliminal cues, intuitional and clinical background just as the student uses the same methods to understand himself.

Several methods have been suggested for validating diagnoses. Allport has recommended the method of congruence in which the "systematic relevance" of incidents is sought in order to determine whether the hypothesis is valid in terms of the personality structure of the individual. A good test of validity of a diagnosis may be the student's tryout of a proposed remedy. This, however, complicates the problem of validating a diagnosis by introducing the concomitant problem of validating the treatment or therapy procedures.

PROGNOSIS

For an individual case, a prediction should be made, when possible, on the basis of actuarial statistics or experience expectancy of students with similar abilities, aptitudes and interests, and from the individual qualities of the student which may make him more or less likely to overcome his particular handicaps. To facilitate

prognosis in the field of vocational and educational guidance, occupational-ability profiles and education-ability profiles have been constructed against which the individual student's profile may be projected. Probability studies in other types of adjustments are not as well advanced and accurate. From the standpoint of prognosis, it is essential in all types of adjustments that deficiencies be understood by the student. Disabilities in the areas of reading, speech and social skills frequently must be corrected before adjustments to other problems can be achieved. Furthermore, such factors materially reduce or increase the likelihood of a student's adjustment and thereby influence his efforts to adjust.

In probability studies of prediction in the area of scholastic achievement, results show that a very small per cent of those students whose average high-school scholastic rank and test percentile rank fall in the lowest quartile of college freshmen make a satisfactory college record. Other studies have shown that more accurate predictions can be made about the prognosis of failure for low-ability students than for those with high college aptitude test scores. High-school grades expressed as a rank in the graduating class is usually the best single predictor of college success as measured by grades—the two correlating approximately at .55. Achievement test and college ability tests correlate with college grades to the extent of approximately .50 and .40, respectively.

Prediction studies of success in schools of law, medicine, engineering, nursing, dentistry and business, based on a battery of special aptitude tests, yield somewhat similar correlations. Since correlations above .70 are very seldom achieved between test batteries and scholastic success, an individual prediction for a particular student has a large standard error of estimate. Horst and his associates have discussed the literature on the prediction of personal adjustment (2).

COUNSELING OR THERAPY

It is in treatment or counseling that the organization and coordination of a student personnel program show to great advantage. The programs of other campus personnel agencies dealing with finance, housing, religious participation and other aspects of student life may be enlisted and exploited for the welfare of the individual. A free inter-referral system makes

the transitional contacts easy for the student except in certain types of emotional maladjustments.

The major approaches to this step in the structure of counseling are: remedial, as in the case of speech, reading or health problems; reorienting the individual, as in the case of certain types of attitude problems; changing the environment, as in securing changes in course regulations and requirements or changing jobs; and giving the individual necessary information which he may lack. All of these approaches may make extensive use of other campus personnel agencies. Counselors endeavor to enlist the cooperation of parents whenever feasible.

Remedial treatment in speech or reading may consist of referral to experts who retrain the client while the counselor continues to see him about other adjustment problems. Students who lack social skills, social contacts or social outlets may be referred to the student activities division for specific help in learning to participate as citizens of the college community. Students with severe personal or family conflicts may be referred to a mental hygienist. Students with financial problems may be referred for loans or scholarships or for employment counseling regarding suitable part-time work.

Reorienting the student may constitute a relatively long and difficult counseling job. For example, downgrading a student's ambition—or, frequently, his family's ambitions—may require many interviews with the client and with one or more members of his family. Assisting an individual to solve an emotional problem calls upon all the skill and background which the counselor has readily available. Catharsis, persuasion, suggestion, emotional re-education, habit retraining and information giving are the techniques generally adaptable to the counsellee. Rogers has recently discussed an adaptation of Rank's "relationship therapy" in connection with the counseling of those students having certain types of emotional problems (3). He says the client needs acceptance in a permissive environment; through talking about his difficulties, he evolves his own solution without being directed toward any solution by the counselor.

Changing certain features or all of the environment may consist in arranging, or having the student arrange, changes in employment, in instructors, in housing or in scope and type of

socializing activities. In the case of exceptional students, it may consist in having requirements waived to cut through a mass of red tape. This type of treatment, often relatively easy, may have sudden and spectacular results in certain counseling situations.

Many students who are thought to have "problems" may be better characterized as not possessing adequate information to achieve adjustment. In such counseling cases, information may be given or the student may be told where he can obtain it. Usually the student is required to take positive steps such as this in order that he may realize he should cooperate in solving his problems and in learning to make decisions independently. The process of re-educating some overly-dependent students is tedious and involved; in other cases, counseling consists of direct, casual and friendly assistance. *The treatment techniques should be adapted to the nature of the adjustment problems and the personality of the student. There is no universal, standard counseling technique or ritual which will prove effective in all types of situations with all types of students.*

FOLLOW-UP

Since adjustment is a continuous process throughout an individual's life span, a follow-up or verification of the counseling outcomes is important for several reasons. First the counselor desires to know whether the student has successfully solved the problem or problems which motivated him to seek assistance. In addition to this the counselor attempts to discover whether the student has incorporated into his behavioral pattern more appropriate techniques for solving new problems which subsequently may have arisen. Furthermore, follow-up work is not only an integral part of the total counseling process, but it also serves as the stepping-stone to a general evaluation of the adequacy of diagnostic and treatment techniques.

There are two general types of follow-up case work. Through the use of a tickler file, both student and counselor may be reminded of appointments. This is especially desirable when a long series of interviews seems appropriate or when interviews are either irregularly or widely spaced in time. Such a method permits the counselor to review the case notes before the contact and to plan the content and direction of the interview as far as his participation

is concerned. A second type of follow-up consists of a periodic re-reading of all case records to determine those cases which remain uncompleted. Students who have not exploited counseling contacts may thus be identified. Interviews may be arranged for the purpose of evaluating progress and continuing the counseling if the student desires to do so.

EVALUATION OF COUNSELING

Because of the complex and highly individualized nature of counseling, and because of the difficulty in defining adequate criteria by which the success of counseling may be judged, the results of most evaluative studies in this aspect of student personnel work have not been of crucial importance. In many studies only one criterion, such as grades, graduation or "success" on the job, has been used to gauge the effectiveness of counseling. Certain limitations inhere in such criteria; for example, low-ability students who achieve insight through counseling and withdraw from college to seek either training at a more appropriate level or suitable employment may be judged to have adjusted very adequately, but, in such cases, this adjustment cannot be estimated by such criteria as grades or graduation from college. Furthermore, grades are not equally meaningful for all "bright" students. Even job success is difficult to estimate, let alone measure, because of local conditions on the job, social and economic conditions which obtain at a given time and the unreliability of employers' ratings. Although research methods are improving in experimental design and in scope, the results of evaluative studies should be considered as tentative. Few of these investigations have studied counseling outcomes in relation to later life and occupational adjustments.

Research studies have consistently shown that students select more appropriate occupational goals after being counseled. In these studies, the choices of students tend very definitely to become more realistic and more suitable to each individual's basic measured potentialities. However, there is some evidence indicating that students planning to enter the professions but lacking the requisite abilities are more reluctant to change vocational goals than those planning to enter sub-professional fields.

British follow-up studies, carried out over a long period of time, show a consistent trend

toward more adequate on-the-job adjustment on the part of those individuals who followed counselors' recommendations based upon an analysis of aptitudes. These studies also show a significantly larger number of subsequent changes in employment to recommended vocational areas by students who originally rejected counselors' suggestions.

Concerning educational improvements, controlled studies have shown that a large majority of counseled students improve scholastic adjustments as indicated by grades in college courses. This fact seems clear both when students' grades before and after counseling are compared and when the grades of counseled students are compared to those of non-counseled students with comparable types and amounts of scholastic aptitudes.

In the area of social adjustments, studies are relatively few and criteria are even less satisfactory than those for vocational and educational adjustments. Exploratory research has indicated that a group of students counseled individually and systematically in college activity participation tends to achieve significantly better social adjustment, as measured by performance on a personality scale, than a comparable group left to its own devices.

Taken as a whole, research studies in the evaluation of counseling outcomes demonstrate that there are significant, measurable differences favoring counseled students when they are compared to non-counseled students of similar potentialities. Research is needed concerning other possible personality differences between these groups. Preliminary research, indicating that counseled students participate satisfactorily in more aspects of campus life than do students who have not sought or received counseling, may provide the framework for investigating and evaluating more comprehensively the role of counseling in a student personnel program.

CREATIVE THINKING. — Creative thinking is the type of thought which is best illustrated in the production of a work of art or the solving of a scientific problem. It is characterized by the four stages of preparation, incubation, illumination or "inspiration," and elaboration or verification. Helmholtz (17) described the first three periods and Poincaré (44) added a description of the fourth. Wallas (57) has clarified the descriptions of Helmholtz (17) and Poincaré (44) by giving definite names to the stages of thought which they distinguished. Creative thought is differentiated from the type of imaginative activity found in reverie or day-dreaming in that it is directed by a purpose or goal. Reasoning by special disciplines and techniques plays an important part in the process, especially in the first and last stages.

The first period of creative thinking is preparation, when the subject is assembling or receiving new ideas (38, 39, 40). During this time the ideas shift rapidly. One's thoughts are not yet dominated by any coherent theme or formulation. A scientist starts to solve a problem and considers its various phases. An artist receives various impressions from what he sees, as a landscape for instance, or from what he hears or reads. The period may be longer for the mathematician, who spends some time laboring over a problem, or for the writer of a historical novel, who collects much factual information, than for the poet, who often receives his impressions in a short time. Preparation is a time when the creative thinker is receiving or gathering his raw material. It may last from a few minutes to months or years.

Incubation is the stage which follows preparation, although it may accompany it. Incuba-

tion is a period in which the problem is laid aside and no voluntary work done upon it, but after this time renewed attention to the problem results in a prompt solution or at least a prompt advance beyond the previous degree of mastery. A mood or idea is being incubated when it involuntarily repeats itself with more or less modification during a period when the subject is also thinking of other topics. It may be indefinitely related to an ultimate goal, as a poet while incubating a mood may have the ultimate goal of writing a poem about it later, or a mathematician may think of one aspect of a problem with the ultimate goal of solving it. As soon as the mood or idea becomes definitely related to a specific goal, we have the third stage of illumination or inspiration. For instance, a poet may be incubating a mood of stillness. All at once it becomes definitely related to the specific goal of rhythmic lines, and then we have the third stage of illumination. Or a mathematician may be incubating one aspect of a problem and then all at once this aspect becomes definitely related to the specific goal of the correct formula and we have illumination. The scientist usually incubates an idea while the poet or artist more often incubates a mood or emotionally toned experience. When we compare the incubation which occurs in the writing of a poem, the painting of a picture, the making of an invention, and the solving of a problem, we find that there are certain characteristics common to this stage of thought. In the first place, no active work is done on the idea or mood that is incubated. The subject thinks of other topics. In the second place, the idea or mood that is incubated recurs spontaneously. In the third place, the idea or mood is more clearly defined at the end of the stage than it was at the beginning, for it has been modified. The length of the period of incubation varies from person to person, and also within the same individual from time to time. The length of the stage ranges from hours or days to months or years. But the generalization cannot be made that it will always last a certain time for a certain person, for under one set of circumstances the period may be only a matter of minutes or hours and under other conditions it may last months or years. It is not surprising that there is such variation in the length of the period of incubation, for there are various factors which influence it. Some of these

would be the nature of the original stimulating situation, the intensity of the emotional reaction set up, and the daily life of the individual, not to mention numerous other factors.

The third stage is that of illumination. It occurs when the idea, which has been incubating, becomes definitely related to a specific goal. It is the period when a poem is composed, or the general solution is achieved. In this period the essential structure is completed. A part of a poem seems to come automatically and spontaneously by itself. Or in the case of a mathematician a new relation to a problem comes all at once. An emotional reaction does not necessarily accompany this period, although it generally does. Rossman (50) and Platt and Baker (43) have shown that the solution to a problem with scientists or inventors is apt to occur at some odd moment when the problem has been laid aside after intensive work upon it. The successful hunch would come suddenly as a flash of insight and is usually of short duration. Blanshard (5) speaks of the "leap of suggestion," Christof (10) of the solution of a problem after an accumulation of psychological products or food for thought, and Portnoy (45) of the third stage in which the artist works with abundant energy.

Elaboration or verification is the final stage. For both the artist or the scientist the idea which is obtained in illumination is elaborated and revised during the last stage of verification. The length of the period may vary from a few minutes to months or years. It may be very slight as in the case of a lyric poem, for instance, or comprise much calculation and checking, as in the case of mathematics.

Although these four stages can be distinguished in the thought process, yet it must be remembered that they may overlap. Incubation often occurs along with preparation, and revision may begin during the period of illumination. In the stage of preparation, while the subject is still receiving new ideas, one mood or idea may be incubated and recur from time to time. Also revision of the lines may start before they are completely formulated.

Creative thought is frequently accompanied by an emotional reaction, although this is not always the case. Hutchinson (19, 20, 21) says that the period of preparation is composed of trial and error activity, false starts on the basis of inadequate hypotheses, random effort, stereo-

typed errors, real, vivid and undermining frustration. In the second stage of incubation (or renunciation) the problem is given up and other activities are interpolated. There may be rising emotional tone and restlessness with a feeling of inferiority. Following incubation is the third stage of illumination, in which an artist often experiences an intense emotional reaction with the corresponding bodily changes, or works in a feverish state as Galli (14) mentions. Others have it to a much less degree or scarcely at all. Likewise in scientific thinking the period of illumination is accompanied by an emotional reaction in many cases. There is a feeling of exultation, adequacy, and finality. Bahle (1) notes that the sudden idea is characterized by its fitness for the problem at hand, feeling of unfamiliarity, capacity for expansion, and its vitality, freshness, and originality. The thinker may feel that the inspiration has come from sources outside of himself because he does not understand the psychological stages of preparation and incubation which have preceded his creative illumination, and he may underestimate his own ability (53). In the final stage of elaboration or revision the attitude has changed from the creative one to the critical attitude. There is the dominance of negative standards of criticism over positive ones.

According to Poincaré (44), Lowes (33), Downey (13), Jastrow (43), Portnoy (45), Prescott (16) and Ribot (48) incubation is a period of work by the subconscious mind. It continues to work when conscious effort has been suspended and is the basis of the ideas of illumination or inspiration. Another explanation of incubation is that no such work is done by the subconscious mind during the resting period, but that interferences and false leads, emphases, and assumptions are given a chance to fade out through forgetting, so that certain relations and possibilities which are invisible to the subject in the active preparation period come into view after a rest. Helmholtz (17) said that the modifications during the period of incubation were due to the overcoming of fatigue and the handling of material in a better manner. Ruger (51) and Meinicke (37) have studied the differences in mental set at the time of discovery. Woodworth (60) states that since the problem does consciously recur from time to time during the period of incubation,

though without effortful work done upon it, partial solutions may be obtained. If illumination comes in a period of intense concentration on the problem, the assumption of previous unconscious work is gratuitous. The freshness or lack of brain fatigue which appears to be necessary for illumination may furnish a sufficient explanation. The thinker may fall into certain assumptions from which he cannot escape as he may on returning to a problem after a rest. Rignano (49) asserts likewise that normal reasoning is produced almost entirely in the conscious state and that unconscious elaboration does not take place at all, since the supposed unconscious elaboration is not in the least fatiguing.

The Gestalt investigations have mentioned the primacy of the whole over the parts. In a study of poetic and artistic creative thought the primacy of the whole over the part was frequently apparent throughout the process from the beginning (41), but in other cases the idea of the whole developed from a detail or part during incubation; which idea of the whole in turn preceded the parts or details brought out in the stage of elaboration.

Creative thought is to be distinguished from other types of imaginative activity, as in phantasy, reverie, or daydreaming, in that it is directed by a purpose or goal. Burr (8) and Prescott (46) have stated that purpose controls the resulting mental activity until the problem is either solved or else given up on account of its difficulty. Such controlled imaginative activity results in the formation of new ideas or solutions. In the integration of the process of reasoning Pillsbury (42) has emphasized the importance of purpose, and Maier (35) has described the direction of goal or end.

The activity of the imagination which results in the construction of new ideas from past experiences has been variously described. The fusion of images or elements of past experience into new combinations has been indicated by Pillsbury (42) when he says that inference or deriving a conclusion always depends on the laws of association. Ribot (48) asserts that creative imagination is due to the property of images to gather in new combinations. Reasoning is the flow of ideas determined by the laws of association according to Binet (4) and Pyle (47). Thorndike (56) writes that reasoning shows the action of the simple general laws of

connecting in cases where the connections are with the elements of the situation rather than with the gross totals, and where the connections compete and cooperate in complicated organizations. Hollingworth (18) speaks of redintegration in reflective thought and of the importance of cues in redintegrating a consequent event or in mere associative reproduction. Sargent (52) describes imagination as the forming of new combinations or patterns out of past experiences, resulting in an original product. According to Wertheimer (58), Wheeler (59), and Koffka (23) an act of invention is the completion of a pattern or configuration which was previously recognized as being incomplete. Reasoning is the reorganization of isolated experiences in terms of a goal. Creative thinking is the successful transposition of a member of one configuration to another, according to Wertheimer (58).

Conditions which favor creative thought are that the time should not be too strictly limited for the thinker, and the problem should be sufficiently difficult. Illumination often appears after the problem has been laid aside for a while and the thinker is engaged in other activities. Rossman (50), Harding (15), Boraas (6), Carr (9), and Platt and Baker (43) assert that conditions as half-asleep, light physical exercise, or the pursuit of activities different from those connected with the problem are important. Periods of idleness in which autistic thinking may promote imaginative ideas are justified according to Britt (7). Ribot (48) asserts that one must first possess the spirit of observation and wide-awake attention which isolates and fixates accident, and Boraas mentions the importance of optimism (6). Tartman (16) suggests that creative thought is aided by relaxing the pressure of ordinary routine to allow more free time and also by making close imitative study of good models.

Lehman (24-32) has shown that in nearly every line of endeavor the majority of the best work is produced between the ages of thirty and forty years. This is true in those lines of work where individual achievement is the primary factor, but it is not so evident in those occupations where other social conditions are important for achievement. In music, drama, art paintings, literature, etchings, chemistry, mathematics, physics, medicine and related fields, inventions, and philosophy the majority of the

best work is produced between thirty and forty years of age. In the case of astronomers and architects the peak is between forty and fifty years. In other fields, where social factors besides individual achievement are important, the best work is more often produced at later ages, as military leaders in the late forties, political leaders in the late fifties, large incomes in the late fifties and sixties. The fact that in almost all the various lines of endeavor, where individual achievement is the most important factor, the peak of production of the highest quality is within a narrow age range between thirty and forty years is evidence that creative thought is of the same essential nature in the different fields. Spearman (54) states that in creative thought the form of mental process involved in creation is everywhere the same; it is always the transplanting of an old relation, and in consequence the generating of a new correlate. Wallas (57), Hutchinson (20), and Lowes (33) likewise assert that creative thought is essentially the same in the different fields of endeavor.

Among other terms which have been used to describe the psychological stages of creative thought, Luzzatto distinguishes three moments, as he calls them, in artistic creation (34). The first is the simplification of reality in the active enjoyment of a natural spectacle or manifestation of human life. This corresponds to the first two stages of preparation and incubation. The second moment is when the simplification of reality is transferred into communicable form which corresponds to the third stage of illumination. Elaboration or verification is the same as his final stage of execution. Similarly, Ribot's (48) first phase corresponds to the stages of preparation and incubation; his second phase to that of illumination; and his third phase to that of elaboration or verification.

James (22) writes that the art of the reasoner consists of two stages: sagacity or the ability to discover what part of the abstract property lies embedded in the original data, and learning or the ability to recall promptly the consequences or implications of the abstract property's consequences. Duncker (36) speaks of analysis of problem, analysis of materials, analysis of goal, solution by resonance, and insight in reasoning. Steps of thought mentioned by Claparede (11) are perception, perusal, inference, and groping one's way or trial and error.

The logical order of steps in reasoning has been brought out by Dewey (12). He speaks of a felt difficulty; its location and definition; the suggestion of a possible solution; the development by reasoning of the bearings of the suggestion; further observation and experiment leading to acceptance or rejection. Billings (3) and Symonds (55) have postulated five somewhat similar steps. Bentley (2), Blanshard (5), and Christof (10) speak in a more or less similar manner of three steps of thought as formulation of task, elaboration, and solution. Scientific descriptions of logical steps of reasoning are not the same as those of the psychological stages of creative thought. For instance, descriptions of logical steps of reasoning do not bring out the need of rest before illumination or the time order of the different stages. The five steps mentioned by Dewey, for example, might all occur in the first stage of preparation, in which the thinker may get an idea, pursue it slightly, and reject it.

E

EAR, THE.—The organ of hearing is conveniently divided into three parts, i.e.; (1) the external ear, which consists of the auricle and the external auditory canal; (2) the middle ear, including the tympanic membrane, the eustachian tube, the tympanic cavity, the antrum and the mastoid cells and (3) the internal ear, consisting of the osseous labyrinth, the membranous labyrinth and the auditory nerve.

THE EXTERNAL EAR

The Auricle is composed of scroll-like folds of cartilage covered by skin. The posterior curved rim is called the helix, and anterior to this rim and extending along its entire length is a Y-shaped elevation, the antihelix. The limbs or crurae of the Y enclose a shallow depression, the fossa triangularis, while the stem curves down and forward to terminate in a small oval elevation, the antitragus. Anterior to the antihelix and with a shorter radius of curvature is found a semicircular depression, the cymba conchae. The cymba is bridged a little above its center by the crus helicis, which fans out anteriorly and below it funnels down to end in the external auditory meatus, which opens into the external auditory canal. In front of the meatus a convex leaf of cartilage, the tragus, is so situated to partly form a protective covering to the opening. The helix terminates below in a soft pad of tissue containing no cartilage and is called the lobulus. It is thus seen that the structure of the auricle, with its concentric folds of cartilage funneling down and into the external auditory meatus, is well adapted to collecting and directing sound waves to reach the inner structures of the ear.

The External Auditory Canal is directed inward and slightly forward for a distance of about 36 mm to end at the tympanic membrane. Its first portion is composed of cartilage which changes to bone as the tympanum is approached. It is lined by closely adherent cutis which contains sebaceous glands and hair follicles along the cartilagenous portion of the

canal whose anterior wall is crossed by two or three fissures (fissures of Santorini) containing a few muscle fibers and connective tissue which serve to render the auricle more moveable. The canal conducts sound waves which have been collected and directed by the auricle to the tympanic membrane. Sound waves thus canalized are amplified by the structures of the external ear which prepare them for transmission and perception.

THE MIDDLE EAR

The Tympanic Membrane closes the external auditory canal, being attached to a groove (sulcus) in the annulus and pitched at about a forty-five degree angle inclining downward in both vertical and horizontal planes. The membrane is oval in shape, about 9 mm in diameter and 0.1 mm thick. It is composed of an outer layer of cutis reflected from the canal, a middle layer of inelastic radial and circular fibrous tissue mats and an inner layer of reflected mucous membrane from the cavity of the middle ear. The handle of the malleus is imbedded within the structure of the membrane. The upper portion of the membrane which is attached to the Rivinian segment (where the annulus tympanicus is absent) does not possess a middle fibrous layer and is known as Shrapnell's membrane, pars flaccida or membrana flaccida in distinction to the less elastic remainder of the drum, membrana tensa. As viewed through an otoscope the tympanic membrane appears as a delicate translucent curtain possessing a pearly sheen which is slightly moveable when a column of air is directed against it. Shrapnell's membrane is limited below by the posterior fold, the circular protruding short process of the malleus and the short anterior fold. The handle of the malleus appears extending downward and backward from the short process to end in the slightly invaginated center of the drum (umbo) from which a cone of reflected light is observed extending downward and slightly forward towards the rim.

Sound waves reaching the tympanic membrane cause it to vibrate in a manner roughly similar to the open palm tattoo which vibrates the head of a Cuban drum.

The Eustachean Tube extends from the tympanic cavity to the nasopharynx a distance of about 36 mm. The tympanic portion is osseous and the pharyngeal section (24 mm) is membrano-cartilaginous. The tube has flaring orifices at ends and a narrow constriction (isthmus) where the osseous section joins the cartilage. The canal of the tensor tympani muscle lies above and the canal for the internal carotid artery lies internal to the osseous portion of the tube. The cartilaginous section is lined with ciliated columnar mucous membrane which sweeps the secretions towards the pharyngeal orifice in the same manner that the para-nasal sinuses are normally evacuated. Normally the eustachean tube is collapsed and opens only during the acts of swallowing and yawning when the palatal muscles are contracted. Air may be forced in the tube by forcibly blowing the nose against a nasal obstruction or sneezing when nasal obstruction exists. The levator palati, the tensor palati and the salpingo-pharyngeus are the muscles which act upon the tube. The function of the eustachean tube is to equalize air pressure on each side of the tympanic membrane. By the ciliary action of the lining mucous membrane effete material is prevented from entering the middle ear through the pharyngeal orifice and inflammatory exudate is removed from the cavity of the middle ear when it is diseased.

The Tympanic Cavity is bounded above by a thin plate of bone separating it from the middle fossa of the skull frequently containing dehiscences through which the dura may come in contact with the mucous membrane and below by a thin plate of diploic bone in close proximity to the jugular bulb and the carotid artery. Externally the cavity is bounded by the tympanic membrane and small portions of the temporal bone, while the anterior wall contains the opening of the eustachean tube and the canal for the tensor tympani muscle, and below the inferior edge of the opening of the eustachean tube the wall is in close relation to the canal for the internal carotid artery. The posterior wall of the tympanic cavity presents the opening to the mastoid antrum (aditus), beneath which is the pyramidal process within which the stapedius muscle is located. The inner

wall of the cavity forms the outer wall of the labyrinth and contains the oval window (fenestra vestibuli) closed by the foot plate of the stapes, the round window (fenestra cochlea), a projection formed by the basal turn of the cochlea (promontorium), a prominence formed by the facial canal (facial ridge) and the prominence of the lateral semicircular canal. The mucous membrane lining the tympanic cavity and its adnexae consists of flat nonciliated cells except along the gutters of the drainage channels where it changes to the ciliated columnar type. The tympanic cavity is conveniently divided into three parts, i.e.; (1) the epitympanic space (attic) lying above the level of the upper margin of the membrana tensa, (2) the atrium situated between the levels of the upper and lower margins of the membrana tensa and (3) the hypotympanic space which is located below the level of the tympanic membrane.

The tympanic cavity contains three small bones, the ossicles, supported and bound together by five ligaments and forming a chain connecting the tympanic membrane with the oval window of the labyrinth. The ossicles named in their order from the tympanic membrane are, the largest malleus (mallet), the smaller incus (anvil) and the smallest stapes (stirrup). The stapedius muscle arises from the interior and posterior tympanic walls and is inserted in the neck of the stapes, so that its contraction tilts the anterior end of the footplate outward, the posterior portion of the membrane of the oval window acting as a fulcrum, the power being applied at the head of the stapes. The tensor tympani muscle arises above the osseous portion of the eustachean canal and from the upper wall of the cartilaginous section of the tube, passes upward and backward within its canal to emerge in front of the oval window from where it curves around the cochlear process and crosses the lateral wall to be inserted into the inner and anterior surfaces of the handle of the malleus. The tensor tympani muscle acts in opposition (antagonist) to the stapedius, and when the former contracts the handle of the malleus together with the tympanic membrane is drawn inwards, the head of the malleus and incus are tilted so that the footplate of the stapes is pressed into the oval window, thus increasing the pressure on the perilymph. In this way the intralabyrinthine pressure is regulated. The

chorda tympani nerve on its way to join the lingual nerve passes through the tympanic cavity, and the facial nerve lies in close apposition to the inner and posterior walls of the cavity. The arteries of the middle ear are derived from the internal carotid, the middle meningeal and the stylomastoid.

The Antrum is a small reservoir situated between the mastoid and the tympanic cavity of which it is an embryological part and with which it communicates through the aditus ad antrum. The antrum receives drainage from the mastoid cells.

The Mastoid Process consists of an outer shell of hard bone situated behind and below the auricle. Beneath this shell the bone becomes shot with numerous communicating air cells (diploic bone), presenting a variable and complex pattern which usually communicate through devious channels to the antrum.

The vibrations of the tympanic membrane are transmitted to the articulated chain of ossicles and conducted to the oval window where they are transmitted to the perilymph. During this process the amplitude of the wave is reduced one third while its force is increased one and one half times.

THE INTERNAL EAR

The Osseous Labyrinth may be conveniently divided into the vestibule, the semicircular canals and the cochlea.

The Vestibule is a tiny irregularly shaped space communicating with the tympanic cavity through the oval window which is closed by the footplate of the stapes. Its area contains and abuts the following structures, i.e., the utricle, the saccule, ostia of the semicircular canals, the ampullae of the semicircular canals and the opening into the scala vestibuli.

The Semicircular Canals consist of three looped channels about 2 mm in diameter with bulbous endings (ampullae) each placed at right angles to the others. With head erect the external canal is horizontal, the anterior canal is vertical from within outward and forward and the posterior canal is vertical outward and backward.

The Cochlea is a bony spiral resembling a snail shell composed of two and one-half convolutions (tubal length of about 40 mm) wound around an axis (modiolus) in the form

of a hollow cone which contains the cochlear vessels and nerves. Every convolution is divided into an outer channel (scala vestibuli) and a lower inner channel (scala tympani) by a lamina of bone extending out from the modiolus. An opening (helicotrema) establishes communication between these two channels.

The Membranous Labyrinth is enclosed within the osseous labyrinth and may be divided into the vestibular or static labyrinth and the cochlear or acoustic labyrinth.

The Vestibular Labyrinth is formed by the membranous semicircular canals and two sacs, the utricle and the saccule, united by a narrow duct. The utricle communicates with the three semicircular canals by five openings and with the saccus endolymphaticus by a duct which unites with a similar one from the saccule. The saccule communicates with the cochlear duct and indirectly with the utricle. The membranous labyrinth is surrounded by a fluid, the perilymph, and encloses a similar fluid, the endolymph. The cilia of the hair cells project into small calcium deposits (otoliths) which rest on the sensory nerve fibers within the utricle and saccule. The otoliths act as a mechanical stimulation to the hairs, varying with the position of the head to possess a kinetic function concerned with posture. The nerve-end organs of the membranous labyrinth are distributed over certain spots known as cristae, papillae and maculae.

The Acoustic Labyrinth is concerned with sound perception and consists of the terminal nerve filaments of the cochlea, the acoustic nerve and the auditory center in the brain. The cochlear duct is the membranous portion of the cochlea and is a long tube closed at both ends which communicates with the saccule by means of a canal. A thin membrane closes the upper end of the cochlear duct (Reissner's membrane). The vibrating or resonating portion of the cochlea is a tense band of fibers (basement membrane) forming the floor of the duct. Endolymph is secreted by a vascular network (stria vascularis) located in the spiral ligament (thickened periosteum), and the perilymphatic duct connects with the subarachnoid space.

The Auditory Nerve is formed by two branches, the vestibular and the acoustic, in the internal auditory canal. It carries vestibular and acoustic impulses to the medulla oblongata of

the brain where the centers communicate with other centers controlling muscular activity, thus establishing reflex arcs of equilibration and motive response to sounds. The vestibular branch sends filaments to the utricle and the superior ampullae of the semicircular canals. The cochlear branch sends filaments to the sacculle and to the ampulla of the superior semicircular canal. The cochlear distribution of the auditory nerve together with its supporting structure is called the organ of Corti of which there are about 2000 cells. The nervous hair cells of the organ of Corti are arranged on the basement membrane in four or five rows, a row of modified rod-shaped supporting cells being arranged between the last and next to the last row. The nerve fibers extend from the base of the hair cells into the canals to the modiolus to join the spiral ganglion and from there into the internal auditory canal forming the acoustic branch of the auditory nerve. The hair cells are stimulated through the medium of the hairs which project from the free ends. Higher pitch tones are taken up by the hair cells near the beginning of the basal coil, while those of low pitch disturb hairs near the apex of the cochlea.

The blood supply of the labyrinth is very important from a clinical standpoint. The vessels are derived from the basilar through the labyrinthine artery and are end arteries having no anastomoses nor collateral circulatory channels, so that obstruction stops circulation. The veins find their exit through the aqueductus cochleae and vestibuli.

Sound waves are transformed into fluid waves at the oval window where the movement of the perilymph brings about a sympathetic vibration of the basilar membrane, various regions being made to vibrate by fluid waves of certain lengths and frequencies, which, in turn, stimulate the overlying hair cells to form an impulse in the cochlear nerve which is conducted to the brain where it is interpreted as sound. Slight movements of the basilar membrane (low intensities) excite the external hair cells, while relatively greater excursions of the membrane (high intensities, probably over 30 decibels) are required to excite the internal hair cells, so that tones of different pitch excite the hair cells in different regions of the cochlea, i.e., the lower the tone the higher up in the spiral of the cochlea are the receptors excited.

The angle of the impact of the otoliths in the sacculle and utricle creates a sensation which, upon being interpreted by the brain centers, gives consciousness as to the relative position of the head to the line of gravity and to the plane of the earth (static equilibrium). The nerve endings (*cristae*) in the ampullae of the semicircular canals are concerned with the regulation of equilibrium when the head is moved (rotated, rocked or tilted) and thus preside over dynamic equilibrium.

The normal range of hearing for man is from 16 to 22,000 double vibrations (cycles) per second. As age progresses the upper range is normally lowered to about 16,000 cycles. The difference in intensity of sound is measured in decibels, the smallest increase in sound intensity detectable by the normal ear. Ten decibels would mean a tenfold increase in sound intensity. Normally sound is conducted about twice as long through the ear by air conduction as it is by bone conduction, i.e., through the bones of the skull. The appended table indicates some common frequency ranges.

HARMONICS		SOUNDS	
	Cycles		Cycles
Vocal	80-1200	Thunder .	20-40
Strings	42-3000	Waterfall .	40-50
Piano	20-4608	Voice	256-2048
Wind	60-4608	Phone ...	250-2750
		Radio	50-6000
		Film	50-8000
		Insects ...	14000

HAROLD T. GARARD, M.S., M.D.,
Lewisburg, Pennsylvania

EDUCATIONAL PSYCHOLOGY: THE ROLE OF MEASUREMENTS.—Educational psychology is a mixture of beliefs, fragmentary data of a superficial nature, some keen insights, and a developing technique of exploration and evaluation. Except for the few ideas borrowed from psychology and psychophysics, it started the present century with little more than some outworn beliefs derived from instructional practices that had survived a trial and error process. It was quick to borrow the mathematical techniques of analysis, from those of correlation to those of analysis of variance, and to adapt them effectively to its own use. In this process of adaptation numerous refinements have been worked out and some of the

mathematical procedures greatly extended, as in factor analysis.

It is in the field of measurement, however, that it has made its unique progress, for in this field it could borrow but little beyond the techniques of psychophysics. Its progress as a science has been limited by the necessity of creating and refining all its own measuring instruments as well as of isolating the qualities to be measured through the development of such instruments and the statistical analysis of the data derived from their use. Whatever ideas make up the content of educational psychology today beyond or in contradiction to earlier beliefs have been largely derived from such data. As advances are made in the techniques of measurement and analysis of data, and actual principles underlying mental activities are discovered, these newer ideas—such as maturation of intelligence, readiness for a new subject like algebra through growth, and memorizing ideas mainly through repetition—derived from a very different source than the current practices which follow them, will also undergo marked revision. The level which educational psychology has reached is best reflected by the precision with which measurement of intellectual functions can be made and the adequacy with which such data can be quantitatively analyzed. Since other articles deal with the techniques of analysis, this one will be confined to the development of measuring instruments.

The earliest forms of measurement in education were the subjective evaluation of a child's handwriting, his composition in English, his oral reading of a paragraph or poem, his paragraph answers to questions in history, the oral or written spelling of words and the doing of exercises or problems in arithmetic. The quality of the finished products in handwriting, composition, oral reading and paragraph answers, and the number of correct products in spelling and arithmetic furnished the bases of subjective evaluations without any definite, objective standards.

Out of the handwriting samples, English theses and drawings have come the handwriting scales, English composition scales and drawing scales. In place of the paragraph answers to questions we now have the objective type of questions calling for one or more choices from several suggested answers, one or more blank

spaces in a sentence to be filled in, or a series of statements to be arranged in order for some quality. With this change in form the emphasis has been shifted from recall to recognition, from writing a group of associated ideas if not interrelated ones, to the selection of an idea apparently but not actually stripped of most of its associations and interrelations.

Since the product scales were the first ones to be developed in educational psychology the methods of their construction will be taken up first. In the development of the Thorndike handwriting scales a collection of specimens spreading over a wide range of quality were sorted into piles for merit by a group of competent judges of handwriting. On the assumptions that the variations in assignment of a specimen to different piles resulted from errors of judgment and that these errors of judgment, due to many independent factors, would approximate a normal distribution surface in form, scale values were assigned to each specimen on the basis of the frequencies with which it appeared in each of the contiguous piles.

In the development of the Hillegas English composition scale a more refined technique, the rank order method, was used in scaling the samples. After some 40 specimens of composition writing had been selected from the piles in which a larger number covering a wide range of quality had been distributed by people competent in English, these selected specimens were submitted to a group of approximately 400 teachers of English to arrange in order of merit from the poorest specimen to the best one.

After the arrangements of the judges had been tabulated, the numbers of times each specimen was rated higher than each other one were converted into quartile deviation or probable error values with the use of a probability table. The specimen selected as having a zero value was one that half of the group of original judges considered a composition, while the other half believed it too lacking in merit to be considered a composition at all. If the next better specimen was rated better than the zero specimen by 84.4 per cent of the group of 400 judges, the 84.4 per cent was converted into the probable error value of 1.50. Specimens were selected for the scale that fell closest to one probable error unit apart, or a distance

apart equivalent to a difference noticed by 75 per cent of the group of judges. This technique of constructing quality measuring instruments was later applied in the development of scales for measuring specific qualities of English composition, drawing and sewing. It has also been used in developing instruments for measuring attitudes.

The rank order technique of determining the scale values of samples has not only been shown to possess internal consistency: that is, a specimen somewhat distant from another specimen will have the same scale value, within very narrow limits, whether determined from the percentage of "better judgments" or from the addition of intermediate distances; but the scale values derived by means of it show a linear relationship with the scale values determined by the paired comparison and successive intervals techniques. The basis of these various psychophysical techniques of determining scale values of samples is discussed in detail by Thurstone in his article, "Measurement in Psychophysics."

In the earlier tests involving the use of objective tasks, the list of tasks were frequently mixtures of several types of tasks. There might be a few multiple-choice type of tasks—a statement or question followed by several short, concise answers, one or more of which were acceptable without the subject being told the number to be selected as right; a few single-choice type of tasks similar to the multiple-choice type, except that there was only one acceptable answer and the subject was so informed; a few completion exercises with one or more blank spaces in the sentences to be filled in; a few tasks containing several items to be arranged in order for some quality; and a few matching questions, which were usually poor combinations of the single-choice type of tasks. The score was the number correctly done. On the single-choice type of task there might be a considerable amount of guessing, on the multiple-choice type less but with no possible way of making a correction for the guessing as it varied from one type of task to another. In the earlier tests in spelling and arithmetic the tasks were all of the same type—words to be written or exercises to be done. In the Trabue language-completion exercises the tasks were all of the completion type. In the group mental

tests the tasks in each subgroup were alike but varied from one subgroup of tasks to another.

In the development of the early scales in spelling by Buckingham and by Ayres, in arithmetic by Woody, in language completion exercises by Trabue, and in American history by Van Wagenen, the selected list of tasks were administered to several hundred children in several school grades. On the basis of the assumption that the distribution of a school ability among a large group of children of the same age or in the same grade would approximate a normal distribution surface, since it would probably be the result of a large number of independent factors working together, the percentages of subjects in a grade doing each task correctly were transformed into scale values with the use of a probability table giving the areas of the normal surface of frequency corresponding to each P. E. distance ($x/P.E.$) from the median of the distribution. If 25 per cent of the subjects in grade 5, 50 per cent of those in grade 6, and 75 per cent of those in grade 7 did a task correctly, this task would have a scale value of -1 P. E. in grade 5, 0 P. E. in grade 6 and $+1$ P. E. in grade 7. By determining the P. E. distances between the grade medians on the basis of all the tasks, the scale values for the sixth and seventh grades could be referred to that of the fifth grade by subtracting from each scale value the corresponding grade difference above the median of the fifth grade. The average of the three or more scale values derived from several grade groups would not only give a reasonably stable scale value, one with a probable error of 0.2 of a P. E., but also smooth out minor variations in the grade distributions and make it feasible to cull out erratic performing tasks, such as the few done but little better in a higher grade than in a lower grade. In determining the scale values of the tasks different weights were assigned to the tasks nearer the median value of a grade than to those farther away by different authors, but the practice of using the quartile deviation was followed by all except Ayres, who used the standard deviation.

These lists of tasks with their carefully determined scale values were not actual scales, however, since the scale values of the tasks had no direct relation to the raw score or number of tasks correctly done on the list. The selection

of small lists of tasks evenly spaced apart still yielded raw scores. Only in the case of the Woody arithmetic scales was it feasible to find the scale value for a class, and this required the tabulation of the tasks correctly done by each pupil.

In the meantime the Thorndike reading scale alpha 2 had been developed and a technique devised whereby a pupil's scale score, showing the level of difficulty at which he could do 80 per cent of the tasks correctly, could be obtained from a rather lengthy table of numbers of correct responses to items at successive levels of difficulty. The tasks in this case were direct questions to which the answers could be found in the paragraphs to which the questions referred. Since pupils gave many different answers to each question, scoring keys giving acceptable and non-acceptable answers were necessary. To make the scoring simpler and to insure uniformity of scoring, scoring keys accompanied practically all published objective tests.

From the use of this reading scale two techniques of obtaining scale scores for individual subjects have been developed: the T-score technique and the C-score technique. With the T-score technique, as used in the development of the Thorndike-McCall reading scales, the same assumption of normality of distribution of a school ability like reading is made as in determining the scale values of individual tasks. In this technique, however, it is the number of tasks correctly done for which the scale value is determined. As the list of tasks cannot be changed after the scaling procedure begins, the items must be selected with extreme care for each duplicate form of the scale. After the several final lists of tasks have been administered to several hundred children, preferably of the same age, the number of pupils who surpass each number of tasks correctly, plus one-half of those succeeding with that number of tasks, is changed into a percentage. With a probability table this percentage is changed into a scale value. If 480 out of 1000 children completed more than 19 tasks correctly and 40 more completed 19 tasks, the number to be converted into a percentage would be 480 plus $\frac{1}{2}(40)$ or 500. The percentage 50 falls exactly in the center of the distribution. In the Thorndike-McCall reading scales this point for the 12-year-

old children, to whom the tasks were administered, was set at 50 T-score units, since this point was estimated from available data to be approximately five standard deviations above an absolute zero point of reading ability. By making it 50 instead of 5, and using the standard deviation as the unit, the T-score unit is thus one-tenth of a standard deviation of twelve-year-old children for this scale. If 828 of the same 1000 twelve-year-old children completed more than 12 of the tasks and 26 more did 12 tasks correctly the number 828 plus $\frac{1}{2}(26)$ or 841 is equivalent to -1 standard deviation below the median, hence a raw score of 12 has a scale value of 40, while the raw score of 19 had a scale value of 50.

Although the list of tasks cannot be altered after the scaling process has been started, there are many areas, such as reading or vocabulary, in which no change in a carefully selected list of tasks will be needed. It offers the advantage that all the tasks set up can be used in the scales, provided a normal distribution of the ability to be measured can be obtained. It is not always feasible to secure an unselected age group, however. In that case a large group can be measured for some closely related function and a close approximation to a normally distributed group selected on which to determine the T-score values of each number of tasks correctly done on each of the duplicate lists. All duplicate lists have to be given to the same group and all culling of items and arranging of tasks from easy to difficult ones in each list done before the scaling procedure is undertaken.

When the usually selected list of tasks used in an experiment is subjected to the T-score technique, it reveals wide differences in the spacing apart of the raw scores and the questionableness of applying refined statistical techniques to data such that the second standard deviation from the mean in terms of the raw scores may be as much as three standard deviations from the mean in terms of the T-scores. The consistency and equality of the unit of measurement in the T-score scale cannot be tested internally but only by applying it to groups that are known to yield a close approximation to a normal distribution in a closely related trait or by checking it with the C-score units to be described next, that can be tested for internal consistency or same proportion correct at all

levels of difficulty and for equality of units or units of the same size throughout the range of the scale.

From data derived from the Thorndike reading scale alpha 2, it was noted by Kelley that the proportions of correct answers at successive levels of difficulty away from the 50 per cent level tended to conform to an ogive curve, the curve that is obtained when the lower half of the normal distribution curve is reversed in direction. On the basis of this insight the Kelley-Trabue language-completion exercises alpha and beta were developed from the original Trabue language-completion tasks and some additional ones. These lists extended over a range of ten quartile deviations with five tasks spaced one-fifth of a quartile deviation apart within each quartile deviation on the scale. On the basis of the ogive curve and the proportions of tasks correctly done at the lowest and highest quartile deviation intervals, it was possible to predict the number of tasks that would be correctly done at all lower and higher quartile deviation intervals of difficulty. Then a technique was developed whereby, on the basis of the numbers done within each of the ten quartile deviation intervals and the predicted numbers in all other intervals, the level of difficulty at which an individual could do just half of the tasks attempted could be calculated.

The next step was the development by Van Wagenen of tables for making the predictions and combining them with the numbers correctly done to find the 50 per cent level of attainment. Later tables were developed for making the predictions at the unattempted levels on the basis of the numbers done at all attempted levels, combining these predictions with the total numbers correctly done within the range attempted and deriving the 50 per cent level directly from the number correctly done within the limited range of the test. This step made the C-score scales as simple to use as the T-score scales,—reading the scale score on a table from the equivalent number correctly done. The range of difficulty may even be limited to tasks of the same difficulty, in which case the scale is a horizontal one in contrast to the vertical scale with the tasks evenly spaced apart throughout the range of the scale.

The close correspondence between the actual

proportions of the tasks correctly done at each level of difficulty by large numbers of individuals making the same C-score and the theoretical proportions based on the ogive curve in the case of reading for comprehension, vocabulary, abilities in arithmetic and ranges of information not only substantiated the method of finding the C-scores from limited ranges of tasks but provides a technique for determining the scale values of the tasks that are independent of the distribution of the abilities in the group from which the scale values are derived. By basing the scale values only on the proportions doing each task correctly in the case of the individuals in the middle of the group in ability, variations resulting from skewness at the extremes are avoided, regardless of whether they result from biased selections of cases, from differential instruction for dull and gifted children, or from constriction of the range of abilities, as has been found in the spelling abilities of a grade or age group. However, the results of only a limited proportion of the total group tested—the 10 to 20 per cent of individuals in the middle of the group in ability,—can be used, but a much higher degree of precision in scale values can be obtained.

Even at the beginning of this century the fundamental basis of the C-score technique had already been anticipated. The French psychologist Binet, in the first publication of the Binet-Simon individual mental examination, had selected the tasks for each age level on the basis of the proportion of children who were able to do them. The mental age of a child was determined by substituting for each task missed at a lower age level a more difficult task correctly done at a higher age level until all the blank spaces had been filled. The present Stanford-Revision of the Binet-Simon individual examination was built up on the same basis but with larger and more representatively selected age groups. The present method of finding a child's mental age by starting with a basic mental age at which all the tests tried are done and then adding two months for each task done out of the six at each mental age level gives the same mental age as filling in the blank spaces. The child's mental age is thus the level at which 50 per cent of the tasks attempted can be done. The assumption underlying the technique is that just as many more difficult

tasks will be done above this level as easier ones below it will be missed. The C-score technique goes one step farther in assuming that the distribution of the proportions of tasks correctly done at each level will approximate the percentages on the ogive curve, an assumption that has the support of a large amount of evidence. The individual mental examination is thus a C-score scale, with the mental year as the unit of measurement.

The simplest form of the C-score scale would consist of an unlimited range of tasks, starting at an absolute zero point and continuing indefinitely at equal intervals apart, like the inches on a yardstick. With such a scale merely counting up the number of tasks correctly done would indicate the level of difficulty at which 50 per cent of any number of tasks attempted at that level of difficulty could be done correctly. Such an instrument, however, would include too many items over the long range of at least 200 tasks spaced one-tenth of a quartile deviation apart. Even if it were possible to establish an absolute zero point of an ability a large proportion of the tasks would, for any individual, be either so easy that there would be some missed due to carelessness or else so difficult that the individual would give up before the upper limit was reached. For this reason the possibility of limiting the range of task difficulties to that appropriate for a grade or age group of individuals is highly advantageous where such a limitation can be made without any appreciable loss in precision or accuracy. The C-score technique makes it feasible to keep the tasks within any desired range of difficulties, with any number of tasks within that range so long as they are evenly spaced apart in difficulty or with the same number of tasks at each level of difficulty within the selected range of difficulties, and at the same time incorporate in the scoring keys a correction for the element of guessing when the single-choice type of task involving guessing is used. Also new tasks may be substituted for old ones of equal difficulty without changing the C-scores derived from the scale.

As the C-score scale can be broken up into limited ranges of task difficulties, different ranges have been given to the same group of individuals and the instruments tested internally for consistency and equality of the unit of meas-

urement throughout the range of the scale, just as a yardstick might be tested by cutting off the first foot and then seeing if the remaining two feet would give the same amounts of length for different things as the original three-foot yardstick gave. Even when there is no overlapping of tasks difficulties from one range to another in scales administered to the same group of individuals, the median C-scores on different ranges lie within the standard error of the mean derived from one of the limited ranges as often as would occur as a result of random selection.

The C-scores not only make it feasible to compare gains made at different levels of attainment and to compare attainment levels with norms with precision and a known degree of accuracy, but also to refer to tasks on the scale having the same difficulty value as the C-score of the individual. Thus it is feasible to see concretely just what kind of tasks an individual can do correctly in half the attempts he makes or with any other percentage of correctness, and also to see concretely just what the norms for successive age or grade levels mean in terms of task difficulties.

The C-score has one limitation in common with the T-score, however, which only the use of the long form can overcome. While the tasks are equal distances apart in difficulty and the unit is a uniform one throughout the range of the scale, the use of a limited range of task difficulties yields C-scores that are not evenly expressed apart. Those near the center of the scale may be one unit apart, those somewhat farther from the center one and a half units apart, and those at the extremes two and even two and a half or three units apart. The distances apart, however, are expressed in terms of the unit that is of equal size throughout the range of the scale. The T-scores and C-scores resemble the readings from a yardstick with the marks at one inch, two inches, three inches up to 12 inches, then at 14 inches, 16 inches up to 26 inches, then at 29 inches, 32 inches and 36 inches. This feature is a result of limiting the range of the task difficulties. It is in this respect that the C-scores and T-scores differ from raw scores and z-scores or standard scores. These give the appearance of being equal distances apart because the numbers are at unit distances apart, when they are actually far more unevenly

spaced apart than the raw scores on the C-score scales. The T-scores and C-scores indicate just how far apart the measures are, which makes them usable for all refined statistical analyses.

The distinction commonly made between the T-score scales and the C-score scales, that the T-score scale is based on the standard deviation and the C-score scale on the quartile deviation, is an entirely fallacious one. The mental age on the Stanford Revision of the Binet-Simon individual mental examination is a C-score based on an age unit, the score on the Thorndike C. A. V. D. intelligence examination is a C-score based on the standard deviation as the unit of measurement, while the score on the Van Wageningen unit scales of aptitude is a C-score based on the quartile deviation as the unit of measurement. Both the standard deviation and the quartile deviation have been used as the unit of measurement in the T-score scales.

The T-score is also confused by some authors with the z-score or standard score. The z-score is obtained directly from the raw score on a test by dividing the difference between the raw score and the mean of the raw scores by a standard deviation calculated from the raw scores. The distances between successive raw scores on a test are very unequal and tend to grow much larger toward the extremes due to the clustering of the items around the center of the test and the spreading apart of the items in difficulty toward the extremes of the test. The standard deviation calculated from such a variety of units is utterly lacking in quantitative meaning and bears no relation to the variations in distance apart of the raw scores. The procedures of changing the unequal distances apart of the raw scores into the larger unit represented by the standard deviation of raw scores has no effect upon the inequality of the original raw-score units. The same defects are present in the z-scores or standard scores that were present in the original raw scores; not a single one was removed by the application of magic.

On the basis of the techniques so far discussed it will be feasible to consider more adequately other kinds of measures and indices widely used in education and educational psychology. The one most commonly used is the grade norm or standard. This is usually the median of the raw scores on a test that has been

given to many children in successive school grades. Although these norms depend on the selection of the groups, they provide definite numerical levels with which individual scores may be compared for interpretative purposes. By the grade designation 4.2 is meant two months beyond the beginning of the fourth grade. Their value for comparisons is limited by the fact that different subjects are given different amounts of emphasis in different grades, that a pupil's attainment level is more dependent upon his mental age than upon his grade location, and the subjects change from year to year above the eighth grade. In a large city, groups of pupils in the same grade in different schools may differ by as much as two and a half years in median mental ages.

Nearly all group mental tests and some achievement tests use the age norm or standard. The raw mental test score is compared with the median raw scores of groups of pupils at successive chronological age levels and interpreted as the mental age (M.A.) in years and months to which it corresponds among the median raw scores or norms. The age measure suffers the limitation that at the higher ages the pupils make smaller gains in raw scores than at the lower ages in most of the content used in the mental tests. The common interpretation that intelligence levels off and becomes stationary at the higher age levels as height does is too questionable an interpretation and too simple an explanation in view of all the other factors that might be involved, such as familiarity with the environment, redirection and specialization of interests and dropping out of school.

The educational age (E.A.) is derived from an achievement test in the same manner as the mental age is derived from a group mental test. It suffers from the limitation that a larger proportion of the older and less capable pupils and a smaller proportion of the gifted pupils are found in the higher elementary grades than in the lower grades and that only the less able pupils at ages above 14 tend to be found in the eighth grade.

From these age scores three indices may be derived: the intelligence quotient (I.Q.) or mental age divided by the chronological age; the educational quotient (E.Q.) or educational

age divided by the chronological age; and the accomplishment quotient (A.Q.) or educational age divided by the mental age. The intelligence quotient, which first came into use with the Stanford Revision of the Binet-Simon individual mental examination, is a measure of the general rate of learning from birth to the time the mental test from which it is derived was given. Since the distribution of intelligence quotients tends to approximate a normal distribution surface for an age group, their distances apart tend to be approximately equal. Any conditions of learning, whether internal or environmental, that influence this general rate of learning temporarily can have but a small effect on the intelligence quotient. It varies, however, with the variations in content from one kind of mental test to another and becomes highly unstable at the higher ages when amounts of the test content learned tend to decrease from year to year. The educational quotient is a similar measure of the general rate with which the content of a school subject has been learned over a period of years. Variations in emphasis from grade to grade tend to produce greater changes in the educational quotient than occur in the intelligence quotient, but these changes are too much smoothed out by long time effects to be of use in evaluating a pupil's school accomplishment over a limited period such as a year. The accomplishment quotient is a measure of the relation of the rate of school learning to the rate of learning in general. Since it, too, covers the period since birth even marked changes in the relation over any one year can produce only small changes in the accomplishment quotient. The per cent placement, first used in the Minnesota preschool scales and the Van Wagenen unit scales of aptitude is an index based on the assumption of a normal distribution of a function in an age group. It shows the percentage of the way a child stands between the lowest and highest of a representative 1000 children of his age. It is thus a precise measure derived from age and scale score tables, but independent of age limitations. Any variation in it, apart from errors of measurement, indicates the amount of change in position in a function independent of the changes in position of others. It can be determined independently for each kind of content in a test, and a cor-

rected weighted average may be obtained that makes all the partial ones comparable with that for the total test. All the indices so far mentioned are based on 100 as normal or average.

Another widely used index of an entirely different nature is the percentile rank or an individual's rank in his own group changed to what his rank would be among one hundred individuals in a similar group. It is readily found by multiplying his rank in his own group by 2, subtracting 1, dividing the remainder by two times the number in his own group and then moving the decimal point two places to

the right ($P.R. = \frac{2R - 1}{2N} \times 100$). Unlike the

per cent placement or intelligence quotient, the distances apart in percentile ranks increase from the middle percentile rank of 50 toward the extremes in quite the same manner as do z-scores or standard scores and raw scores. It can be used for interpretative purposes but even for this use its value is more limited than that of grade norms or age norms.

The use of precise measurements is not only essential to secure precision in experimental work, but the analyses of the more precise measurements of mental functions are contributing quite as much to the advancement of educational psychology as the use of the more refined statistical techniques in the analysis of experimental data. The growth studies carried on over a period of several years, such as those of young children in the Child Welfare Institutes, the Harvard growth study with several hundred children over a period of several years with the individual mental examination, and the Minnesota growth study in several separate mental functions with several thousand children in grade 4 through 12 over a four year period, have provided a wealth of information regarding changes in rates of learning. Likewise the analyses of the proportions of items done at different levels of difficulty by children of the same mental level but of different degrees of brightness and in different school grades have contributed considerable information regarding the relative effects of nature and nurture upon changes in attainment levels.

EDUCATIONAL PSYCHOLOGY: THE ROLE OF STATISTICS.—Just as in

any other science, progress in educational psychology has been the result of insights. In the accumulation of ideas statistics has played a double role: the arrangement of measurements in statistical tables and the analysis of such rearranged data which make many insights possible; at the same time statistics affords a technique of determining the dependability of the insights. The use of statistical techniques has centered around three main problems: the analysis of data assembled in investigations and experiments; the development of measuring instruments; and the quest for underlying causal factors. The last phase has been a highly specialized one and its use of statistics confined to a small group of specialists in analyzing mental measurements and reading measurements. The earlier techniques of correlation and partial correlation proved inadequate; the later, more promising techniques of factor analysis, still in the formative stage, are discussed elsewhere (see Multiple Factor Analysis). The statistical procedures and assumptions involved in measurement are taken up in the article, "Educational Psychology: the Role of Measurement (*q.v.*)". The present article will deal with the statistical processes that make the discovery of information and the determination of its dependability feasible.

The simplest procedure is the arrangement of data in the form of a distribution table containing one or more arrays or columns, with the measures-intervals at the left and other measures-intervals, such as ages by years, or discrete categories, such as sex groups, at the top. When the measures are entered according to selected intervals in both directions, as on a scatter-graph, the table shows the trends in both the measured functions and also the relation between the measures in the two functions. When the original measures are arranged in scatter-graphs, the calculation of measures of central tendency, variability, and relationship is greatly facilitated.

The simplest statistic or measure derived from other measures is the percentile or point within an interval on a scale on the smaller side of which the expressed percentage of measures lies, assuming that the measures within each interval, such as a year, a month, or three inches, are scattered evenly along the interval. After finding the per cent of the cases needed to reach the desired percentile, the cases are counted up to the nearest point reached without including more cases than the required per cent. The difference between the number counted and the required number is taken as the numerator and the number of cases within the interval as the denominator of the ratio by which the size of the interval is multiplied. This amount added to the beginning point of the interval gives the desired percentile. The most commonly used percentile is the 50 percentile or median. From the 25 percentile and the 75 percentile the interquartile range is found. This is the number of intervals or units between the 25 percentile and the 75 percentile points, and includes the middle 50 per cent of the cases in the distribution. The quartile deviation (*Q*) is obtained by dividing the interquartile range by 2. In a normal distribution of cases, the quartile deviation is referred to as probable error (*P. E.*), since it shows the limits within which the chances are even that any measure selected at random from the distribution will fall.

Although the median and the quartile deviation have been effectively used in many investigations to show trends—changes in central tendency and in variability in one function corresponding to changes in a second function—the arithmetic mean and the standard deviation have been used in the more refined techniques of experimentation based upon random samplings of populations.

The arithmetic mean, a point within an interval on a scale on either side of which there is an equal amount of weight, rather than an equal number of cases as with the median, is found by dividing the sum of the measures by their number. If the intervals or the measures are beginning-point measures, such as a 12-year-old (meaning "having lived at least 12 years, and usually somewhat longer"), the obtained mean is found by adding one-half of the size of the interval to the calculated mean.

Instead of dealing with the measures as collected in their usual original form, they are referred to the arithmetic mean as a point of reference and expressed in terms of the number of units they are above the mean or below the mean. These are also the differences between the original measures and the mean, or the deviations from the mean as well as the expression of the original measures referred to the mean as a point of reference. It is these newly expressed measures or deviations from the mean that are the units of all analytical work, even though the procedures and their formulas may use the original measures or the variations from a guessed average.

The standard deviation or sigma is the number of units represented on the base line of a normal surface of frequency between the perpendicular line at the mean, cutting the surface into two equal parts, and the perpendicular dropped to the base line from the intersection of the two parabolas constituting the bounding line on either side of the mean. This distance is 1.4825 times the size of the probable error and includes 34.13 per cent of the cases on either side of the mean, in contrast with the 25 per cent on either side of the median in a probable error or quartile deviation of a normal surface of frequency. It is found by squaring the deviations, finding the sum of the squares, dividing this sum by the number of cases, and then finding the square root. The sum of the squares of the deviations divided by the number of cases or the mean of the squares of the deviations is the variance.

The arithmetic mean may be more readily obtained by using a guessed average selected near the center of the distribution, and the sum of the variations from this guessed average divided by the number of cases. This correction added algebraically to the guessed average gives the obtained arithmetic mean. The variance may also be readily calculated from the guessed average and the variations from it. The variance equals the sum of the squares of the variations divided by the number of cases less the square of the correction *delta*, while the standard deviation is its square root. The variance may also be found from the original measures by finding the sum of the squares of the measures, and then dividing this sum by the number of cases and subtracting the square of the sum

of the measures divided by the number of cases. The standard deviation may be found by taking the square root of this result.

When there are two series of measures of the same trait for the same individuals, the original measures of the second series are usually designated Y , their mean \bar{Y} or M_y , the deviations y , the variance SD_y^2 , the standard deviations SD_y , and the variations from a guessed average n . The pair of deviations (x, y) for each individual may be multiplied together and their algebraic sum divided by the number of cases to obtain another variance, which is the variance of the individuals or the variance of either group of measures or total variance, less the variance of the errors of measurement (included with the true variance within the total variance). The ratio of this true variance or variance of the individuals to the product of the two standard deviations is the Pearson product-moment coefficient of correlation, usually designated r . When the two series of measures are duplicate measures of the same individuals made with different instruments, the variances are theoretically equal and the product of the two standard deviations equals the variance of either. Consequently, the coefficient of correlation in this case, called a reliability coefficient, is the ratio of the true variance to the obtained variance, and the variance of the errors of measurement will be the variance of the measures less the true variance. Since the variances of the x measures and the y measures are seldom exactly equal, the standard error of measurement may be obtained from the formulas SD , error of the x measures equals SD_x times the square root of $1-r$ and SD error of y measures equals SD_y times the square root of $1-r$.

The product of the deviations, or of the measures referred to the mean as a point of reference, may be obtained from the variations from a guessed average by multiplying the variations together, finding their algebraic sum, dividing this sum by the number of cases, and subtracting from this result the product of the two *delta*s. When the original measures are used, the true variance or p is the sum of the products of the original measures divided by the number of cases, less the sum of the original measures in each series divided by the number of cases.

With these simple processes one may proceed to analyze series of measures to determine whether one set of conditions produce better results than another. To do this one requires an initial and final set of measurements for two or more groups working under different conditions; one group, called the control group, working under the usual conditions; the other group or groups working under selected sets of conditions with all other conditions the same as those of the control group. To determine whether the set of conditions under which any group works produces better results than is produced under the usual conditions one needs to compare the gains made by the different groups. Instead of determining the gain for each individual in each of the groups, one determines the arithmetic means of the initial and final measures of each group, subtracts the initial means from the corresponding final means to obtain the mean gain of each group and then subtracts the mean gain of the control group from the mean gain of each of the experimental groups. The statistical calculations are thus simple and straightforward: finding the initial means for each group, the final means, the mean gains and the differences in mean gains.

With these results at hand it now becomes a matter of determining how dependable the differences are and to what elements in the conditions they may be due. In the first place the scores used are inaccurate and usually very coarse or even crude. To obtain a reasonably refined set of measures would require a test of many items of the same difficulty values or equally spaced apart in difficulty and extending over a wide range of difficulty values. Such a refined list of tasks would still yield inaccurate scores since any list of tasks would be at best only a sampling of the total list of available tasks. If the tasks in a pool from which the sample might be drawn were all of the same difficulty, did not duplicate one another and were known by just one-half of the subjects tested, less than half of the subjects would be likely to obtain a score of just half of the tasks in the test even though each one knew just half of the tasks in the pool. In such a case, the standard error of the score would be the square root of n times $\frac{1}{2}$ plus $\frac{1}{2}$, in which n (the number of tasks in the test) is the exponent of the binomial expression $\frac{1}{2}$ plus $\frac{1}{2}$ to the n

power. If the test consisted of 100 such tasks, the standard error of the scores would be the square root of $100/4$, or 5 tasks. This is the same as the standard error that would be obtained from a group of subjects with different levels of ability given duplicate sets of 100 items at the same level or levels of difficulty and without duplication of items from the first to the second test, if the variance of the products of the deviations were subtracted from the total variance of the scores on either test and the square root taken or if the variance of the scores on either test were multiplied by the reliability coefficient and the square root taken. From the probability tables giving the proportions of the total surface of frequency corresponding to x/SD , this standard error of 5 may be interpreted to mean that any individual in the group had 68.26 chances out of 100 of making a score between 45 and 55 and that his chances were even of making a score between 46.62 and 53.37. In interpreting individual measures the standard error of measurement is of great importance, which makes it all the more necessary that it be not confused with the coefficient of reliability, which is merely a device for finding the standard error of measurement.

Since with the same number of items in a test the standard error of measurement remains constant for that level of difficulty, within the limits of its probable error, it follows that the wider the spread of abilities in a group the larger will be the variance of the measures of the group and the larger the true variance or variance of the individuals, and also the larger will be the ratio of the true variance to the total variance of the measures, since they increase at the same rate. Consequently the size of the coefficient of reliability is a function of the spread of abilities in the group rather than a measure of the quality of the test. It is also a function of the duplication of items between a test and its duplicate test, since the duplicate items do not enter into the variance of the errors of measurement but into the true variance only while entering into the total variance of the scores, thus increasing the coefficient of reliability still more.

In comparing the difference between the means of an experimental group with that between the means of the control group, the question at once arises, "Could the difference be

tween the differences have occurred just as a matter of sampling and errors of measurement?" Although we cannot obtain true statistics for the population from which the samples were drawn, we can obtain estimates of these true measures from the obtained measures or statistics. From the standard deviation of a sample we can estimate the standard error of the mean or the standard deviation of the means of the samples from the mean of the population by dividing the standard deviation of the sample by the square root of the number of cases in the sample less one. Likewise, from the standard errors of the two means we may obtain the standard error of the difference between the two obtained means or the standard error of the mean of the gains by taking the square root of the sum of the squares of the standard errors of the two means if there is no correlation between the initial and final measures or no spread of abilities in either the initial or final measurements.

Whether the same test or a duplicate test is administered at the end of the experimental period, there is likely to be some relationship between the scores of the same individuals on the initial and final tests or some spread of abilities. The effect of this relationship or spread of abilities is eliminated by subtracting two times the correlation coefficient between the initial and final measures times the standard errors of the two means from the sum of the squares of the standard errors of the two means. This standard error of the difference between means or of the mean difference is the square root of the sum of the squares of the deviations of the differences between initial and final scores from their mean, divided by the number of differences times the number of differences less one.

From the standard errors of the differences between the means or of the mean gains of the experimental (E) and control (C) groups, the standard error of the difference between the mean gains of the two groups may now be determined by taking the square root of the sum of the squares of the standard errors of the mean gains of each group, or in terms of the deviations of the original measures from their respective means.

The difference between the mean gains of the two groups divided by the standard error of this difference gives the value of t or the value

of the ratio of the difference to its standard error. This t corresponds to x/SD in the probability table, from which the chances that the difference in gains might have been the result of random selection of the two groups may be readily determined. When the number of cases is small Student's Table for t should be used. If the t is only .6745 the chances are even that the difference might have occurred as a result of the random sampling. When t is 1.96 there are still 5 chances out of 100 that it might have occurred as a result of selection, and even when t is 2.58 there is one chance out of 100 that it might have occurred as a result of random selection of samples.

The value of t may also be interpreted as indicating that the chances would be less than 5 in 100 at the 5 per cent level of confidence of getting a t as large as 1.96 times the standard error of the measure in a random sampling of that size or that the chances would be less than one in 100 at the one per cent level of confidence of getting a t 2.58 times the standard error of the measure in a random sampling of that size. Both the Snedacor table and the Fisher Z-table give the values of t at the 5 per cent level of confidence and at the one per cent level of confidence, while the Fisher Z-table gives them at the 2 per cent level of confidence and at each 10 per cent level of confidence up to the 90 per cent level of confidence.

When the individuals in the experimental and control groups have been matched on the basis of initial measures and some criterion highly related to the function under investigation the value of t may be found directly by dividing the mean gain or the difference between the means of the final measures of the two groups by the standard error of the difference. From this type of experimentation one cannot infer that the effects found would tend to hold true for a population or for a random sampling of it, but it does make feasible the determination of differential effects upon controlled selections of cases, as illustrated by the differential effectiveness of certain methods of instruction with bright and less bright pupils.

To make an effective use of achievement test results in relation to mental test results for individuals as well as predicting success in vocations from earlier tests, it is necessary to set up a basis of predicting normal attainment levels from mental or aptitude test levels. Such

predictions are based upon locating the normal expected levels of attainment in a column of Y measures corresponding to the individual's mental level indicated by an X measure. This is done by determining from data in both functions the slope of the best fitting straight line of y on x or the regression equation of the line y on x. The regression coefficient may be used for locating the points on the regression line. The predicted value for any point of the regression line corresponding to the value of X is the mean of the Y measures plus the regression ratio times the difference between the X measure and the mean of the Y measures. Any number of factors with different weights may enter into the prediction. The weights of such factors are obtained from the p's and the SD's and the solution of the simultaneous equations in which the values of p and SD have been substituted.

The standard error of the actual Y measures from such predicted measures or the points on the regression line y on x, corresponding to each X measure, is the standard deviation of the Y measures from the predicted points on the regression line. It may be obtained by multiplying the standard deviation of the Y measures by the square root of one minus the square of the coefficient of reliability. Since the variance of the Y measures from the mean of the Y measures minus the variance of the Y measures from the points on the regression line equals $r^2 SD_y^2$, $r^2 SD_y^2$ is the variance of the points on the regression line from the mean of the Y measures; and the variance of the Y measures from the points on the regression line is the variance of the Y measures minus r^2 times the variance of the Y measures. The coefficient of correlation squared is the ratio of the variance of the points on the regression line from the mean of all the measures, multiplied by the number of cases in the columns, to the variance of the Y measures from the mean of all the Y measures. In case the relationship between the two sets of measures is not linear, the variance of the Y measures from the means of the columns will differ considerably from the variance of the Y measures from the points on the regression line.

The variance of the Y measures from the means of the columns is most readily determined with the use of the correlation ratio *eta*. The square of this ratio is the variance of the

means of the columns from the mean of all the Y measures, multiplied by the number of cases in each column, to the variance of the Y measures from the mean of all the Y measures. The variance of the means of the columns from the mean of all the Y measures is the sum of squares of the deviations of the means of the columns from the mean of all the Y measures, times the number of cases within the columns corresponding to the X measures, divided by the total number of cases. The variance of the Y measures from the means of the columns is the variance of the Y measures from the mean of all the Y measures, minus the square of the correlation ratio, times the variance of the Y measures. The difference between the coefficient of correlation and the correlation ratio is an index of the extent to which the means of the columns departed from the points on the regression line.

In situations in which we desire to determine whether the differences between a set of observed frequencies and a set of theoretical frequencies could be regarded as chance fluctuations, chi square may be calculated to show the probability or proportion of times that as great a divergence as that obtained would occur as a result of chance fluctuations. From the value of chi square and the corresponding degrees of freedom, the proportion of times that the divergence of the observed frequencies from the theoretical frequencies would be exceeded in random samplings of the same size, may be obtained from Elderton's table for testing goodness of fit. As a measure of the divergence of fact from hypothesis, chi square may be used in connection with a contingency table or to test the goodness of fit of a distribution to a normal surface of frequency. It is the sum of the squares of the differences between the observed frequencies and the theoretical frequency at each interval divided by the theoretical frequency. The theoretical frequencies are the proportions of the areas of a normal surface of frequency that corresponds to each $x - x/SD$ distance from the mean on the base line. In the chi square table of Elderton the P corresponding to the chi square and the degrees of freedom ($n-1$) shows in what proportion of cases any value of chi square will be exceeded. The chi square technique is, thus, a means of determining the probability that the two or more distributions of measures used in

an experiment are random samplings of a population. The chi square may be used in testing a group of means for homogeneity or a group of arrays for homogeneity of variance. When capacity tests as well as initial tests of attainment are used, the groups of subjects may be selected to approximate a normal distribution and tested for homogeneity by means of the chi square test.

Before an experiment is set up, it may be important to discover whether the proposed techniques to be compared can produce differences greater than might be found among random samplings of a population. To accomplish this function, analysis of variance has come into use in educational psychology. In samples of the same size drawn from a homogeneous population the mean variance of the samples or columns in a distribution table plus the variance of the means of the samples equals the variance of the total sample and the variance of the means multiplied by the number of cases in a sample equals the mean variance of the samples. Also from N times the variance within the columns divided by $N-k$ degrees of freedom and from kn times the variance between columns divided by $k-1$ degrees of freedom, as well as from N times the total variance divided by $N-1$ degrees of freedom, the variance of the population from which these statistics were derived may be estimated, from the first two independently since they are exclusive. Hence, if the estimated population variance or the mean square obtained by dividing n times the sum of the squares of the deviations of the means from the mean of the total sample by the degrees of freedom ($k-1$), differs from the estimated population variance or the mean square obtained by dividing the sum of the squares of the deviations in the columns from their respective means by the degrees of freedom ($N-k$), to no greater extent when attempts have been made to produce differences in the samples than would occur if the samples were selected at random, the null hypothesis that the samples may have arisen from chance fluctuations in drawing them from a homogeneous population is substantiated and further work of the same kind or quality is not likely to produce significant results.

The comparison of the estimates of the population variance may be made directly from the mean square or estimated population variance

obtained from the squares of the deviations of the measures from the group or column means, divided by the corresponding degrees of freedom ($N-k$); from the mean square or estimated population variance obtained from the squares of the deviations of the means from the mean of all the measures, multiplied by the number in the group, divided by the corresponding degrees of freedom ($k-1$); and also from the mean square obtained from the squares of the deviations of the measures from the mean of all the measures divided by the corresponding degrees of freedom ($N-1$). The ratio obtained by dividing the larger of the two mean squares—mean of the squares within the columns or mean of the squares between the columns—by the smaller may be compared with the values of F in Snedecor's table for the corresponding degrees of freedom to ascertain whether so wide a divergence would occur among random samplings at the one per cent level or even at the 5 per cent level of confidence. The level of confidence may also be found from Fisher's Z -table by setting $z = \frac{1}{2}(2.30258 \log_{10} F)$.

Instead of finding the standard error of a difference in mean gains of an experimental and control group in the usual way, t may be calculated by analysis of variance from the difference between mean gains and the square root of the sum of the squares of the standard errors of the means of the gains in each group, with the estimated SD_M , determined from the mean sum of squares or estimated population variance derived from the variance within columns or F may be calculated from the variance between columns divided by the variance within columns.

When the measures are classified in the columns on the basis of one character and in the rows on the basis of a second character, such as methods in the columns and schools in the rows, with the original selections of experimental groups randomized for both characters, the sum of squares for the rows may be obtained in the same way as for the columns and the sum of squares for both the columns and the rows subtracted from the total sum of squares to obtain the interaction variance or residual sum of squares divided by $(n-1)(n-k)$ degrees of freedom. This is the variance that would be obtained by correcting each column measure by the difference between the

column mean and the mean of all the measures, correcting again each row measure for the difference between the row mean and the mean of all the measures, and then finding the sum of squares for the corrected measures from the mean of all the measures, and dividing by $(n-1)(n-k)$ degrees of freedom. This interaction variance, corresponding to the variance within the columns, is used to test the column variance by finding the ratio of the column variance to the interaction variance, from which the row variance factors have been eliminated, or to test the row variance by finding its ratio to the interaction variance with column variance factors eliminated.

The analysis of variance is not limited to three components but may be extended to a larger number, may include groups of measures within each classification cell, and may, through analysis of covariance, deal directly with the gains as final measures through correction of the final measures for differences in initial measures. These more specialized techniques of analysis of variance as well as those involving the use of the chi square test, partial and multiple correlation, the regression equation, and curve fitting, like those at the basis of mental measurements, could be described in adequate detail only in articles dealing with each. The specialized techniques involved in the development of instruments for the measurement of mental functions are taken up in "Educational Psychology: the role of measurement."

EMOTION.—The interest in human emotions has captivated the greatest minds throughout the history of psychology. Comprehensive theory on this topic has developed slowly, however, and widespread agreement among experts is rare even today. The following historical survey is designed to maintain a general neutrality so far as contemporary controversies are concerned. As an introduction to such a survey some attempt to define "emotion" seems necessary.

The popular textbook definitions of emotion are quite suggestive but are far from being conclusive. Emotion is by some considered to be a stirred-up state of the organism. Others define emotions as emergency reactions. But such definitions neglect a certain difficulty which arises from the fact that both physiological disturbance and situational crisis are matters of degree. At what point does truly emotional behavior commence? Does all behavior have an emotional component? Some psychologists, both ancient and modern, have accepted the thesis that every experience has an affective aspect, and all definite adjustments by the organism include an emotional component. If this thesis is true then obviously the above definitions miss the point. Shall "emotion" remain as an undefined but absolutely basic category?

Behavior in which a great surplus of organic tension, over and above that which is obviously necessary and useful for adjustment, is evident admittedly is somewhat rare. Likewise, those experiences in which affective qualities dominate the field are unusual experiences. And some psychologists would reserve the term "emotional" for these extreme cases. And there are certain gross physiological criteria of the emotional state which fit these extreme cases. For example, animal psychologists regard such behavior as otherwise unexplained defecation and urination to be a sign of emotion or, perhaps, even a component of the emotional state. When more subtle physiological criteria, such as cardio-vascular changes, are used, it becomes difficult to define the limits of an emotional state. In the study of highly complex, socialized human behavior emotion is usually defined in very broad terms. Some would urge even that, wherever concern is expressed, there is emotion. It has been said that in the expression of all attitudes, even in those cases in which the expressive action is of a subtle, symbolic type, emotion is evident. To evince an attitude pro or con any issue is to be other than unconcerned, other than neutral, and some psychologists define emotion thus broadly.

Historically, no speculative interest may be traced to epochs more remote in time than those to which the interest in emotion has been traced. The pre-Socratic philosophers showed such an interest. Empedocles, for example, taught that love and hate are cosmic driving

forces. The Platonic Eros and the Pauline Caritas are famous. Saint Augustine tended to identify the emotion of bliss with the third person of the Christian Trinity. Pagan and Christian, Stoic and Epicurean, all agreed that the good life is characterized by certain types of emotions, although there was some dispute as to just which types were ideal. The condition of abiding happiness was sought by all.

Descartes (1596-1650) wrote the first important treatise on emotion in the modern epoch. This treatise, *The Passions of the Soul*, attempted to classify the emotions. Descartes advanced the thesis that there are six "primary passions": wonder, love, hate, desire, joy and sadness. Sadness and hatred were conceived as being natural consequences of pain, while joy and love were felt to be natural consequences of pleasure. Descartes argued that continued pleasure generates joy, and that the recognition of the source of this affirmative emotion results in a feeling of love toward the object. Desire to maintain access to the same object emerges later, especially if the relationship in which pleasure had been produced is temporarily threatened. The Cartesian analysis of the negative emotions followed a strictly complementary logic: pain corresponding to pleasure, sadness to joy, hatred to love and negative desire to positive desire. Wonder was placed in a unique class by Descartes, who urged that when emotional consequences much exceed the apparent causes, wonder at the situation is a natural consequence. It was supposed that the limited cognitive perspectives, available to finite minds, result in a condition in which the emotion of wonder must be considered quite normal.

In the centuries which were dominated by the Cartesian rationalism, and in later centuries during which the Romantic movement developed its protest against excessive rationalism, many classifications of the emotions were constructed, and many controversies about the relative worth of emotion versus reason had their day. Such great names as Spinoza and Kant, in philosophy, Rousseau, in literature and educational theory, and, in psychology, Herbart and even Wundt, are identified with classificatory efforts, evaluative efforts, or with both those types of effort in this field. Wundt, who was the chief founder of experimental psychology in the late nineteenth century, nevertheless

assumed a mainly classificatory attitude toward the problems of feeling and emotion, and introduced no revolution in the field. His attempt to classify the feelings in dimensional terms, based on the concepts of pleasantness-unpleasantness, excitement-calm and tension-relaxation, simply represented the culminating point in the logic of classification.

One of the great contemporary controversies concerning emotion sprang from the famous James-Lange formulation. In 1886 the American psychologist Wm. James stated a really revolutionary theory of emotions, and a very similar, but equally original, statement was advanced in 1887 by Lange, the Danish physiologist. Roughly expressed, these theories assert that emotional experience consists chiefly of internal, or organic sensations. Emotion is identified with sensory states having an exclusively organic origin, although their introspective reference may be identified with the external, stimulating circumstance. James stressed changes in the major viscera and, to a lesser extent, he stressed the skeletal components. Lange stressed various vasomotor changes. But, regardless of minor differences in judgment, it soon became clear that henceforth emotion was to be investigated in a very broad psychophysical frame of reference.

After his original statement, Wm. James indulged in a lively polemical effort in support of the theory. At times he argued that subjective emotion may lag temporally behind the bodily adjustments. His view has been caricatured by the saying that one does not run because one is afraid, but rather one experiences fear because one has started running. Yet James did not identify emotion with sensations coming from the skeletal muscles nearly so much as such a caricature might seem to indicate. As noted above, visceral responses received his chief attention. He did, however, tend to account for moods in terms of postural sets.

The most serious attack against the whole James-Lange position came on the neurological front. This attack was spearheaded by the work of W. B. Cannon, an American physiologist who published a series of research reports in the second and third decades of the twentieth century. Many of these were summarized in his book titled *Bodily Changes in Pain, Hunger, Fear and Rage*. The James-Lange theory would have made it necessary to assume that certain

cortical, sensory areas are the direct, neural substrata of emotional experience. But Cannon stressed the rôle of the thalamus and other sub-cortical centers. Certain of his experiments upon infra-human organisms tended to prove that emotional behavior is changed but slightly when afferent links between viscera and brain are severed. Other experiments showed that when parts are extirpated from various sub-cortical regions, the organism's emotional capacities are radically changed. In some cases the removal of the posterior half of the thalamus was associated with the obliteration of most, or all, of the familiar patterns of emotional behavior.

Cannon admitted that cortical factors do play some part in the more complex emotional states. The cortex was thought to inhibit response tendencies based on lower levels. It was thought to modify or reinforce such tendencies in certain cases. But Cannon and his followers have done less than justice to the James-Lange position. Supposing the thalamus to be intact, it might be assumed that in certain cases visceral changes give rise to cortical disturbances which, secondarily, activate those sub-cortical actions which Cannon stressed. Furthermore, such a sequence of events or its reverse, might be modifiable in a variety of ways by the use of conditioned response techniques. Thus the physiological substratum of emotional experience one day may be defined in much more many-sided and dynamical terms than either the James-Lange theory or the Cannon theory is able to provide. Provisionally, both those theories may be thought of as having contributed something toward the understanding of the physiological aspects of emotional actions.

Much recent research in physiology and psychiatry has confirmed the familiar belief that the autonomic nervous system and the ductless glands play important parts in emotional responses. The autonomic system includes those neural groups which are located completely outside the brain and spinal cord. Autonomic ganglia operate with partial independence from the central system. They compose a somewhat self-regulative system which may be divided roughly into two chief functional parts, the sympathetic division and the cranio-sacral division. Between these a partial functional antagonism prevails. One division provides enervations which retard the visceral processes that

the other division tends to accelerate. In the vasomotor responses the same negative reciprocity has been observed. In a manner of speaking, the sympathetic group is dominant during emotional states and the cranio-sacral, or parasympathetic, system is dominant when the organism is relatively quiescent in regard to outer behavior. Speeding of the heart, slowing of alimentary processes, accelerated respiration, increased perspiration, pupillary dilation and those vascular responses which tend to concentrate blood supply in the skeletal muscles, are among the changes which indicate dominance by the sympathetic. This elementary account, of course, involves great over-simplification. In lust the sacral and the sympathetic segments exercise a mutual reinforcement in some regions, but antagonistic action in other body regions. Some psychopathologists believe that many neuroses and some psychoses are caused by a malconditioning of autonomic responses.

Endocrinology supplements neurology in the modern, physiological approach. The most familiar endocrinological influence in emotional responses is that of the adrenal glands. When the sympathetic system is in a high state of excitation adrenal action reinforces its dominance. Unusual amounts of adrenalin are projected into the blood stream and the release of blood sugar from the liver is facilitated, thus making available more energy for muscular use. The gonads, or sex glands, function as ductless, endocrine glands which regulate individual development and action, as well as functioning as duct glands for reproductive purposes. Among other things, the gonads play some part in the maturation of the organism's capacity for sex behavior and sex emotion, and it should not be forgotten that certain other emotions are in part sublimations of sex emotion. The adrenal glands and the pituitary gland play a part in the development of the gonads, and, as a matter of fact, the reciprocal action of these and other endocrine glands is being increasingly stressed. Few endocrine influences of importance to psychology can be identified with the isolated functioning of any one ductless gland. For example, to suppose that emotional apathy would necessarily be caused by hypothyroidism would be considered a fallacy today. Some hypothyroidal individuals are hyperactive and very excitable, while not all

hyperthyroidal persons are highly excitable. Varying influences of other glands and of non-glandular factors make any generalization, based on the condition of any one gland, exceedingly dangerous. Interdependence within the endocrine system and between it and other systems is regarded as the rule in all contemporary diagnostic work.

Contemporary psychology of emotions has by no means become a mere branch of physiology, although the importance of the physiological approach as one approach among many is universally recognized. William McDougall was one recent investigator who was interested only secondarily in physiology. This British psychologist, whose voluminous writings in this field were mostly published in the 1920's and 1930's, was interested in correlating emotions with other aspects of behavior. He had been the one who originally defined psychology as the science of behavior, but his intention in so doing was very different from that evinced by the doctrinaire mechanistic objectivists. McDougall did not intend to surrender to philosophical phenomenology all the manifold data of the subjective sphere. Rather, his program for modern psychology included respect for every type of data which might throw light on the dynamics of actual behavior. In this programmatic position he has been seconded by such American psychologists as Woodworth of Columbia, and by some American followers of the Gestalt school, which originally was a German monopoly.

In his *The Organization of the Affective Life*, McDougall stated that every driving motive, whether it be a largely innate propensity, or a learned tendency, has a specifically affective component, along with a cognitive component and a conative component. For example, associated with the sex drive is the emotion of lust, and associated with combat action is the emotion of anger. The emotional components are reported by human introspectionists, and in the behavior of lower organisms the emotional components are expressed by certain parts of the total goal-directed action. For example, escape activity does not in its moderate forms strongly express fear but escape activity augmented by profound visceral changes, and associated with such phenomena as pupillary dilation and certain characteristic vocalizations would express fear. McDougall has inferred

that the affective component is present whenever striving occurs, but that this component is greatly intensified if the goal seems unattainable or difficult to attain. Thus all escape action would involve a component of fear, but the so-called narrow escapes would involve the most intense fear. Besides the affects which are bound to particular types of conation, McDougall believed that there are certain more generalized affects. For example, elation accompanies successful strivings of many types, especially if the goal is being achieved despite opposition. Similarly, depressed feelings may accompany progressive failure in many spheres of endeavor.

Finally, the McDougallian theory of sentiments presents a doctrine of affective development which conceives of it as proceeding in relationships of correlation and reciprocity with cognitive development and conative development. In the sentiment, many motives which originally were not specific in respect to their objects function together with reference to a specific object. For example, a man's familial sentiment may include love for his home, fear concerning certain menaces to it, anger toward those believed responsible for the existence of menacing conditions, and so forth. The sentiments integrate the unconditioned propensities, inhibit some of them in certain contexts, reinforce certain of them in various contexts and in other ways represent a long process of socialization and intellectualization. Sentiments, once formed, may themselves be integrated in complex relationships of mutual reinforcement, selective inhibition, and so forth, and the total system of sentiments constitutes a hierarchy in which the sentiment of self-regard may be the dominant hierarchy.

The Depth Psychologists who interpret emotions as expressions of unconscious motives have based their theories upon clinical data. Their major contribution is in the pathology of emotional behavior. Thus they have attempted to prove that many phobias, or irrational fears, are caused by repressed memories of traumatic incidents or of socially "shameful" incidents. They have studied the transference of affects from one object to other objects. Freud has asserted that affective attitudes are sometimes disguised to the conscious mind by reversal formations. Thus, for example, a conscious atti-

tude of hate might represent an unconscious attitude of love toward the same object. Also such an attitude as that expressed by the formula "I love X" might disguise a true attitude of hate for X, and a further step in disguise would be for me to assume that another formula is true, namely, the formula "X loves me," and to assert this while denying my basic attitude and also denying the first step in its disguise. In some cases the depth psychologists have presented interesting data to prove that such transformations and retransformations occur, but many psychologists believe that processes of that nature are too often hypothesized *ad hoc* in order to defend a doctrine or to confuse the more naive disputants against some doctrine. Nietzsche, and before him Novalis and Schopenhauer, formulated many of the psychodynamic principles which the Freudians have applied, or misapplied, to so many situations involving psychological or social conflict.

One of the most fruitful contributions to the psychology of emotions was made by Carl G. Jung, the founder of Analytical Psychology. Jung formulated the theory of the psychological complex, and not only has this theory been applied by Analytical Psychologists in their clinical work, but also other depth psychologists have developed modifications of it, and have applied it in various modified forms. Freudians, Adlerians and others made the theory of the complex a point of departure from which they were to reach some novel and important conceptions concerning human personality. Jung thought of the complex as a group of latent ideas, or other response tendencies, linked together by common emotional associations, and tracing back to common experiential antecedents in the life history. (The article titled Jung, Carl G. provides fuller information about Jung's conception of the complex, and about his methods for probing complexes.) The famous Freudian theory of the Oedipus complex and Adler's theory of the inferiority complex applied this basic idea to what those psychopathologists believed to be some common, and perhaps universal, personality patterns.

Janet, the French clinician and academic psychologist who, like Freud, was once a student of Charcot, originated the contemporary stress upon the rôle in psychopathy of self-directed emotions. Janet also stressed the idea

that physical disease, as well as traumatic experiences, may, temporarily or permanently, render the organism incapable of maintaining the more complex, rational associations. The organism, thus hampered, Janet argued, may be dominated in behavior by primitive, highly affective associations, or may behave in a dissociated manner as is characteristic of persons suffering from hysteria. Freud's book titled *The Problem of Anxiety* applies the conception of self-directed emotions in some extremely subtle and highly speculative analyses of clinical material. Eugen Bleuler was another European psychopathologist who placed great stress upon affective factors. He used the term "autistic thinking" to designate emotionally and wishfully directed sequences of ideas. Bleuler also made great use of "ambivalence" as a descriptive category. (The individual's feelings are said to be ambivalent if contradictory affective attitudes are assumed toward a single object.) Another term, made popular by Bleuler, was the term "schizophrenia." Since the 1920's this term has gradually replaced "dementia praecox" as the name for certain psychoses of regression. Bleuler's clinical studies of these conditions emphasized the importance of affective factors. Coriat stated that the feeling of unreality and the feeling of depersonalization are the definitive attributes of the schizophrenic process. (The articles on clinical and abnormal psychology, the autonomic nervous system, and related topics, throw additional light on the rôle of affective factors in psychopathy.)

John B. Watson and other American Behaviorists stated many fundamental questions in the psychology of emotions. Working at Johns Hopkins University, Watson studied emotional behavior in human infants, attempted to define the genetically primary emotions, and proved that emotional responses may be "conditioned." His views enjoyed an extraordinary vogue in the second and third decades of the present century, and for a time Watson was considered by many to be perhaps the leading American psychologist. Sometimes the major behavioristic thesis is stated in somewhat extreme form as follows: "Any response which an organism can make is conditional to any stimulus which can affect that organism's receptor organs." Behaviorists tend to view learning as a recombination of pre-existent elements of response,

and tend to regard conditioning by contiguous presentation of stimuli to be the sole possible cause of learning.

John B. Watson stated that there are three genetically primary emotions, namely, fear, rage and love. Each emotional response was said to consist of definite motor acts, different in each of the three cases. Each primary emotional response was said to be evoked only by one or two unconditioned stimuli. Other stimuli were said to become efficacious through processes of conditioning the primary responses.

These views, admirable for their definiteness, have been criticized in various ways. First, it was reported (by Sherman and others) that trained observers were unable, when applying Watsonian criteria, to differentiate the rage response from the fear response, or either from the response to pain, if they were allowed to observe infants respond under conditions in which they could not perceive the stimulus in operation, nor perceive the total context of the behavior. Second, various investigators demonstrated that the fear response, even if originally it is stimulated only by loud noises or by loss of bodily support, nonetheless may more easily be conditioned to some new stimuli than to certain other new stimuli. (For example, animals more easily become objects of fear than do inert objects.) Third, it was found (by Wm. Stern and others) that other stimuli than those mentioned by Watson, and in fact almost any sudden, intense stimulus and, later on, any radical surprise may produce that catching of the breath, eyelid closing, vocalization, etc., which Watson has identified as the fear response. Fourth, the genetic question as to whether the only native responses are those present in earliest infancy was raised, and certain components of sexual behavior were cited as constituting one possible exception among many. Fifth, although it was admitted that an original response may be conditioned to a new stimulus by simultaneously presenting the original with the conditioned stimulus several times, the question was raised whether similarity between stimulus patterns may not secure transference, and whether association by similarity is not more important than association by contiguity. Sixth, it was asked (by Gestalt psychologists) whether in the more complex affective behavior may be found the same ele-

ments which occur in simpler behavior, or whether on the contrary entirely new elements are added and all the old elements are transformed. Seventh, it was asked how the reflex theory could be applied to individual differences in average affective tone, and to the more enduring personal moods.

To John B. Watson belongs the great honor of having initiated that at once objective and genetic approach to emotional behavior which has dominated so much fruitful research in the contemporary period. Many of the most serious criticisms of Watson's own specific statements presuppose the use of methods similar to his method. American investigators like Sherman were the first to criticize his theory from the objective and genetic viewpoint. Early emotional behavior, observed Sherman, is diffuse and general in character and does not reveal highly differentiated fear, rage and love patterns. Stratton, another American investigator, stated that excitement is the genetically primordial human emotion. He also pointed out that in the adult diffuse excitement often precedes or follows after the more specific affective responses.

A systematic genetic theory has been stated by Bridges, who accepts and elaborates upon Stratton's general position. Bridges observed emotional behavior of infants and children during and after the nursery-school period. She found that the primary emotional responses may be characterized no more specifically than as follows: first, there is neutral excitement; second, in certain circumstances excitement is tinged with delight; and third, in other, specified circumstances there is distressed excitement. Stimuli which later might produce definite fear or rage responses, at first produce only a distressed excitement which may be differentiated from excitement with delight, but not from certain responses to stimuli which adults define as producing pain. Maturation and learning lead to the progressive differentiation of emotional behavior. From delight emerges affection directed toward various objects, and from distress emerges object-directed anger, fear and disgust.

Bridges regards emotional development as a component part of social development. The socially mature individual has a wider repertoire of emotional responses than the less

mature individual shows. Socialization involves the progressive differentiation of emotional patterns, and the acquisition of conventionalized modes of emotional expression.

American psychologists are now investigating various specific affective action patterns. Only a few examples may be given. In the late 1930's Landis and Hunt investigated the familiar startle-pattern in great detail, observing both human and infra-human subjects. This pattern includes bending the knees, leaning forward, abduction and pronation of the upper arms, clenching the fists, closing the eyes, and other changes. Violent stimulation produces the patterned-responses, and Landis and Hunt found that expectancy may modify the action but not entirely eliminate it. They found that a similar pattern, but if anything a more complex one, appears in the behavior of the higher sub-human mammals. Strangely enough, the startle-pattern seems to be less variable in man than in other organisms. Important individual differences, and variables related to the different types of stimulation were discovered. Landis and Hunt measured many aspects of this action pattern with great accuracy. They used an ultra rapid motion picture camera to make their observations of temporal factors more precise. This work may be taken as typical of a certain class of investigation which has become popular in the United States. The literature includes accounts of somewhat similar studies of affective action patterns connected with sex situations, connected with situations in which disgust is evoked, connected with laughter-evoking situations, and many other types.

Among the more promising work should be mentioned Lund's study of weeping. This American investigator found that weeping by human adults usually occurs in complex, social stimulus-situations. Weeping is not characteristic of deep depression such as is found in certain psychotic states. Nor does unalloyed grief usually include weeping behavior. Grief alleviated by sentimental reminiscences, pity alleviated by some encouraging factors, or tragedy which includes an aspect of comedy may evoke weeping. This study indicates that, like laughter itself, weeping is most likely to occur in situations having some contradictory or incongruous aspect. A comparative study of weeping and laughter might have an important outcome

for theoretical advancement in this general field. Lund is to be commended for stressing in his research the more complex levels of affective action. At these levels individual psychology and social psychology most clearly interpenetrate.

Helge Lundholm's recent book on the psychology of art titled *The Aesthetic Sentiment* is an important theoretical statement in the psychology of affective evaluation. Lundholm points out that in the fine arts a "taste for affect gain" is indulged and cultivated both by the artist and by the appreciative spectator. He points out that many other activities by men under conditions of civilization are motivated partly by a desire to attain emotional tension rather than by a desire to achieve any practical goal or any immediate release of tension. He describes some affective responses which may be evoked by isolated parts of the esthetic object, and discusses the relationships between the various parts. In most meaningful paintings, he urges, one object is the dominant center of attention and empathic feeling, and this dominant object provides the clue to the emotion which must pervade any harmonious experience of the totality. Affects evoked by subordinated parts reinforce or harmoniously counterbalance the feeling which the dominant object evokes. That some esthetic values are based upon the release of repressed impulses is admitted, but a psychoanalytic theory of esthetic value is ridiculed as being naive because one-sided. Certain geometric and logical categories are found to be involved in the esthetic judgment along with affective factors. Specifically esthetic emotions are interpreted with reference to the formal characteristics, but it is shown that the formal characteristics must be experienced in a particular way if esthetic value is to be realized. The esthetic sentiment is therefore considered to be a highly complex capacity for a certain type of experience within certain supporting situations. The sentiment has a variety of roots in genetically primary human nature, but many aspects of the mature sentiment are acquired through experience and practice, and Lundholm admits that there are important cultural variations. This systematic statement in the psychology of esthetics by the present chairman of the Duke University department of psychology may be regarded as a sample of the

kind of task psychology must undertake if it is to achieve in larger measure that broad, humane usefulness which its greatest devotees have always hoped it might one day realize.

Temperament is a major aspect of personality, and is a major category of the psychology of emotion. For some psychologists it is a descriptive category, and for others it is inferential. A person's temperament might be defined as the average quality of his emotional experience or emotional expression. But it might be defined rather as a generalized affective set in the personality as it is known through making inferences from the behavioral data. The two viewpoints concerning temperament could be combined by the hypothesis that the characteristic affective set of a person, although it is complex and may be partly self-contradictory, nevertheless is usually evinced by a characteristic personal mood which in turn is expressed in the constant aspects of the individual's affective behavior. Philosophically inclined psychologists, like Felix Krueger and William Stern, have insisted that all mental processes operate within an affective matrix. If this matrix is unique to the individual, then it would be his characteristic personal mood. Such a mood would be the most constant manifestation of his temperament, while the more fleeting affects would also express the temperament in so far as they are uniquely characteristic to the particular individual. Far from regarding all emotion as a form of disturbance, writers like Krueger and Stern consider the object-directed cognitions as being disturbances upon or within a totality which is essentially emotive in character, or which may be called "affective" if the term "emotive" is to be reserved for application of those very intense affective phenomena which have only a short duration. This viewpoint is reinforced by the fact that some experiences are entirely affective. For example, there are no salient cognitive elements in the state of intense ecstasy. Possibly in certain states of extreme motorial quiescence the affective aspects also monopolize the field.

Few American psychologists view temperament in this light. Although the term is commonly used to stand for the affective aspect of the total personality, this aspect would be considered by most American psychologists to be a system of native and acquired capacities for

affective responses. Such a system might become thoroughly fixed and difficult to modify even though it were highly inconsistent. Emotional fickleness might become an enduring trait of the personality. Radical shifting of moods might be the usual thing. Most American psychologists believe that temperament is the outcome of processes, and conditions future processes. Emotion-provoking situations induce the formation of habitual affective response-tendencies. The prior structure of the individual, however, determines what affective response will be elicited by a particular situation. That there are characteristic personal moods in well-integrated personalities none would deny. These moods might be primarily determined by idiosyncrasies of native structure, or might be determined primarily by very much generalized habits of affective response.

A. N. Whitehead, the famous contemporary philosopher, accepts the thesis that emotion is a universal and necessary factor in experience. Each occasion of experiencing involves, Whitehead states, integrating data into an emotionally satisfying pattern. In the phenomenological part of William James' system of psychology, a very similar position was taken. Feelings were said to express tentative groping toward more definite cognitive associations. Feelings were said to be the transitive factors in the stream of consciousness. Neither James nor Whitehead seemed to realize that long-range personal moods express evaluational orientations. The type of patterns which are achieved in any life experience and also characteristic failures to achieve pattern must have profound consequences for the development of a personal temperament and the characteristic personal moods.

Social psychology is only now realizing the importance of affective factors as expressions of culture and its evolution. Much research along this line may be predicted for the immediate future of social psychology. Emotional behavior in animals is always oriented toward momentary situations. Human emotions, on the other hand, sometimes presuppose relatively enduring schemata of social values. Animal rage appears in particular rivalry-situations, but enduring human hatreds must be explained in trans-situational terms. Some hatreds and jealousies express human rivalry in the en-

deavor to achieve higher social status. There is also a status-referent pride and admiration, shame and disgust, comedy and tragedy. Classical Greek tragedy could never have been appreciated emotionally by the members of primitive, communistic tribes. And what was tragic for Greek pagans might be almost comic, in some cases, for Christians in the Apostolic age. Worldly criteria of status gradually gave way to supernatural criteria. When an individual realizes that perhaps any existent criterion of status is merely provisional, his major social emotions will no longer be status-referent but may become history-referent or, if his attitude is activist, they may become quest-referent. In any moment of social history some hierarchy of values must be dominant if social confusion is to be avoided and cooperative work is to continue. But there is an evolution of evaluative attitudes and, as Nietzsche pointed out, there may be occasional rapid "transvaluations of values." Social psychology should thoroughly investigate the status-referent emotions, their emergence from the merely situational passions, and their modification through later, social and technological crisis situations. (See the article on Social Psychology.)

Today, as ever, happiness, the most universal affective value, is the chief practical concern of those who are interested in understanding emotions and the laws of affective action. The problem of the social and technological conditions which could make personal happiness be more general, deep and secure is fundamental for any integral applied psychology. This problem sooner or later emerges in discussions of the psychology of education, the psychology of industrial relations, the psychology of values, the psychology of religion and other branches. In the light of its findings concerning the affective life modern psychology must contribute to the criticism and evolution of social systems, ideologies dominating cultural groups, work procedure and personal philosophies of life and programs of daily living. Modern psychology today has mastered through a prodigious amount of research and theorizing many facts and principles related to affective processes. And while further investigation of particular, specialized problems is continuing, the greatest contemporary need seems to be the shaping of all this material into a comprehensive system in

terms of which practical programs for its application in the human quest for happiness may be worked out.

EXPERIMENTAL PSYCHOANALYSIS.—Experimental psychoanalysis exists only as a body of results from psychological experiments and objective investigations which have been instigated by psychoanalytic theory or which, by sheer chance, are relevant to psychoanalytic generalizations.

As a branch of science, psychoanalysis consists of a method of observation, a body of generalizations about personality development, and, intertwined with these generalizations, a body of motivational theory. Although psychoanalysis is the only approach to date which has provided a way of viewing behavior and the life history of individuals in broad perspective, as a scientific method it is unsatisfying to those

who judge it by the standards of physical science. The free-associations and dreams which constitute its raw data form a voluminous verbiage almost impossible to record and to make available for the inspection of others besides the particular psychoanalyst listening. The inductions from such data can be colored to an unknown degree by personal predilections; they lack the objective and interpersonal checks taken for granted in other branches of science. Moreover, since the subjects of psychoanalysis are adults, the interpretations of their behavior in terms of their personal histories are explanations after the fact. They cannot be predictive. The fact that psychoanalysis has dealt with aspects of personality development and operations which other scientific approaches had ignored and uncovered challenging results of great significance, has, therefore, made objective and experimental tests of these results important.

The relevant experimental and objective investigations have nearly all been done during the last twenty years, and a majority during the last ten. These studies may be grouped around the psychoanalytic topics to which they are directed or to which they happen to be relevant: the etiological importance of conflict, psychosexual development, description of personality patterns, fixation and regression, the dynamisms and dreams. The brief survey given here must necessarily be incomplete; only outlines of the evidence can be given.¹

THE ETIOLOGICAL IMPORTANCE OF CONFLICT

Although Freud's studies of *"The psychopathology of everyday life"* indicated that conflict between impulses is commonly to be found in normal individuals, he stated categorically that "there is no neurosis without such conflict" (1920, p. 305). Furthermore, he pointed out that there are no specific experiential causes of nervous disorder. The question of whether conflict finds a healthy solution or leads to neurotic symptoms depends upon quantitative considera-

tions, that is, upon the relative strengths of the impulses involved.

This is an explanation after the fact, but the conditioning approach to the production of experimental neuroses in animals, originally developed by Pavlov quite independently of Freud's theory, constitutes at least a partially relevant confirmation. Forcing animals to make difficult discriminations, and other variations of method, have produced behavioral changes in sheep, dogs, and pigs which resemble the neurotic phenomena in human beings. The symptoms include loss of the discrimination, changes from approach to avoidance of the experimental situation, from friendliness to hostility toward the experimenter, cardiovascular symptoms, and pathological sexual reactions. These symptoms, however, have varied according to the animal, the species and the situation (see Liddell, 1944). In the Pavlovian theory of these effects, conflict appears only as the interference between excitation and inhibition. These generalized systems of response tendency are conceptually very different from the instinctual impulses envisaged in the dynamic and subjective approach to psychoanalysis. Liddell's theory of etiology emphasizes the self-imposed restraint to which the animals are submitted in the conditioning situation. This coupled with the monotonous repetition of a specific pattern of stimulation involving what Liddell considers the trivial but inevitable reinforcement, are conceived to produce the experimental disorders.

Masserman (1943) has criticized the conditioned reflex conceptions of behavior and experimental neurosis, and argued for the significance of motivational conflict. Moreover, he has succeeded in producing behavior disorders in cats experimentally by pitting the hunger drive against anxiety drives produced by a sudden puff of air as the animals start to open the food box. Symptoms in and out of the experimental situation like trembling, restlessness, crouching ("anxiety"), persistent non-adjustive reactions ("fixations"), and avoidance of the food-box ("phobias") were actually exacerbated by increasing the hunger drive, or forcing the animals nearer to the food box. Masserman has made a good theoretical case for motivational conflict in the experimental neuroses produced by the conditioning approach. His own experiments were

¹ For a more complete account, the reader should consult the excellent and more ample reviews by R. R. Sears (1943, 1944) to which this résumé is greatly indebted. Only occasional studies not included by Sears will be shown in the bibliography of this paper. These are indicated by a date after the author's name.

planned explicitly to test psychoanalytic theory, and they supported it.

Recently a program of research designed to determine the quantitative laws of conflict objectively has been initiated by Miller (1944) and his collaborators. No attempt is made to produce disorders. Instead of the subjective approach where the conflicting forces appear as "intentions," "wishes," "urges," and "needs," Miller deals with "response tendencies" the strengths of which are controlled experimentally by way of number of reinforcements, number of hours without food, strength of shock, etc. Animals and children have served as subjects. The results show that the issues of conflict are indeed a quantitative matter as Freud had discerned from the subjective approach of psychoanalysis.

PSYCHOSexual DEVELOPMENT

One of the unique contributions of Freud is his theory and description of personality development. In a sense the free associations and dreams of psychoanalytic method yield data from which can be reconstructed a subjective account of the experiences and conflicts which have resulted in the adult personality structure and symptoms of patients (see French, 1944). These data have been interpreted so as to yield a theory of motivation (erotogenesis), a course of development considered universally human, and a wealth of hypotheses about the experiential sources or personal traits, of the perversions, and of various symptoms of disorder. Objective data relevant to these aspects of the psychoanalytic theory of psychosexual development come from objective studies of child behavior, from life history questionnaire or interview studies, and occasionally from laboratory experiments.

Infantile Sexuality. Basic for Freud's theory of psychosexual development is his libido theory. When he set this forth in the second of his *Three Contributions to the Theory of Sex*, he postulated that the sex drive (libido) is the source of the energy for all positive affectional attachments (cathexis), and also that the impulse to behave sexually is present in the child from birth.

Freud stated that attachment to, or love of, objects (cathexis) always results from gratification of libidinal needs by an external object or

person. Laboratory studies, to be reviewed under the heading of fixation, have shown that experiences of success in children, food reward in animals and adult human beings, and identification with heroes in stories will all produce something akin to positive attachments. Furthermore, experiences of failure in children and electrical shock have produced something akin to negative attachments, avoidance responses or possibly hate. While these studies confirm Freud's conception of the role of gratification and its converse in the formation of attachments, they also contradict his generalization that the energy for them must come from the sex drive, unless, of course, all gratification be considered to have a sexual component.

Although there is abundant objective evidence that a sexual impulse or drive is present in very young children, the details of Freud's description of infantile sexuality must be considered. According to his description, infantile sexual manifestations have three characteristics (1920, p. 587). They originate in connection with the biological functions important for life. They are autoerotic in the sense that they have no external object. The sexual aim, gratification, is under the control of the erogenous-zone. The oral, the anal, and then the genital zone are progressively dominant. From the facts of sexual aberrations, he argued that the similarities in the kinds of behavior oriented toward these zones were too great for chance, and therefore the sensations arising from their separate stimulation must be fundamentally similar, and thus gratification from one zone could substitute for that of another. The curiosity of children, he described as directed primarily toward such topics as the origin of babies and anatomical sex differences. Freud also described children as unable to accept anatomical sex differences, and as universally shocked by their observations. He described masturbation in three phases, the first during the nursing period followed by a cessation, a second, pre-Oedipal, at about the fourth year followed by another cessation, effected by the castration complex, that lasts until puberty when a third outbreak occurs.

The objective data on oral manifestations are not relevant, of course, to Freud's claim that the sensations arising from this zone are similar to

those arising from the genital zone. Nevertheless, certain of the observations concerned with thumb-sucking, which was Freud's paradigm for an infantile sexual manifestation, corroborate his descriptive points. Non-rewarded sucking and mouthing at the nipple has been observed in young children after eating by Halverson and by Jensen, which argues that it is motivated by something besides hunger. Levy's studies of thumb-sucking in children indicated to him that it results from inadequate opportunities for sucking during the regular feeding process, and they led him to postulate a separate oral need for sucking. Observations by Ribble (1944) have supported this conclusion. Levy also found that a pair of pups fed with a large-holed nipple showed the effects of their sucking deprivation by chewing and sucking each other's bodies between meals, and by being far more responsive to a proffered finger between meals than were their litter-mates left with the bitch or bottle-fed through nipples with small holes. The fact that children are temporarily quieted by non-rewarded sucking when hungry argues that it may have some substitutive value for food, but says nothing about the substitutive value of oral gratification for excitement from the anal and genital areas. Interference with sucking behavior produces frustration effects similar to those produced by interfering with other drives.

Freud was apparently led to assume an erotic characteristic of anal sensations by his clinical observation of a correlation between constipation or bowel disorders in childhood and adult nervousness, by the existence of anal perversions, and by psychoanalytic evidence that the anal zone often retains considerable genital irritability for life. In a study of 46 nursery children, which again is irrelevant to the claim of similar sensations, Koch found a low but statistically significant correlation between a measure of constipation secured from parents and the frequency of nervous gestures. If adult nervousness and the frequency of nervous gestures in children be considered equivalents, Koch's study supports the clinically observed correlation. But Koch argued that such emotions as fear and anger reduce gastrointestinal motility and may at the same time eventuate in nervous gestures, a plausible interpretation quite different from that in libido theory.

The writer knows of no controlled objective

evidence relevant to the theory of progressive dominance of the oral, anal, and genital zones, but genital excitability, as indicated by erections in male babies, exists at birth. A possible learned basis for the subjective associations between excitement arising in the three zones found in psychoanalytic data derives from the study by Halverson. He observed the daily occurrence of tumescence in nine male babies varying in age from three to twenty weeks. He found it usually accompanied by restlessness, stretching, or crying from which unpleasantness may be inferred. Furthermore, it was associated with micturition, defecation, with hampered feeding, and also occasionally with thumb-sucking. Halverson argues with evidence that tumescence resulted from bladder pressure, but the simultaneous occurrence of these oral, anal, and genital stimulations might account for later association of the sensations from these areas and thus explain what Freud saw in his subjective data without implying any such innate unity as he assumed. Halverson found detumescence commonly followed by playful behavior or relaxation, from which pleasantness may be inferred, but evidence of "orgasm" quality is lacking.

Observations by Isaacs and others show that oral, anal, and genital impulses frequently get verbalized in social situations with other children and with adults, and that all are accompanied by giggling, defiant aggressiveness and other signs of embarrassment and guilt. These observations fit descriptively Freud's notion of the polymorphous-perverse disposition. The response tendencies are present. But the fact that they are all a source of guilt indicates nothing about their interrelationship other than that they have all been forbidden. On the other hand, the fact that Hamilton found a large percentage of the 200 normal adults in his study of marriage who recalled having felt such polymorphous impulses as anal erotism (34%), urethral erotism (37%), childhood exhibitionism (53%), voyeurism (89%), narcissism (64%) argues strongly for the common existence of the "polymorphous-perverse" impulses.

Observations by Isaacs and the information secured from mothers about their children's questions by Hattendorf confirm Freud's claim that the commonest question of young children concerns the origin of babies, with physical sex

differences next most common. On the other hand, Hattendorf's data indicate that a majority of children between two and five years of age do recognize the anatomical differences in genitalia, which contradicts Freud's claim that they are generally unable to accept these. In a study of children's emotional attitudes toward anatomical sex differences with a play technique, Conn found the majority showing a lack of emotional reaction, but 17 of 50 were disturbed and they worried about the cause. A literal castration complex appears to be far from universal. Studies by Terman and by Landis, *et al.* have shown that a majority of adults consider their childhood sex information inadequate. These data argue that Freud's description of childhood curiosity about sex is true to a considerable degree but his contention of universality constitutes an overgeneralization.

All the aspects of Freud's theory of three separate occurrences of masturbation cannot be tested by objective evidence. However, infantile masturbation or manual manipulation of the genitals has been shown to be common in boys, but not necessarily universal. When Levy questioned the mothers of 49 boys, the mothers of 26 admitted observing masturbation before their sons were three, and 19 admitted observing it during the first 18 months. As Freud stated, manual manipulation of genitals is more common in boys than in girls. In Levy's study, the mothers of only four of 26 girls admitted seeing manual masturbation in their daughters. With a time-sampling technique of observation, Koch also found masturbation more common in nursery-age boys than girls. No longitudinal data on a representative group of children are available to determine whether a cessation of masturbation during later childhood is characteristic or not. That no universal latent period exists, however, is shown by the studies summarized by Willoughby (1937) where a fairly large proportion of both boys and girls had begun masturbation before ten years of age, well before puberty. Moreover, Malinowski found an increasing amount of heterosexual genital play among the Trobrianders during the years of the latent period.

With Sears' (1943, p. 21) conclusion concerning Freud's erotogenic theory, the writer concurs. "The notion . . . boils down to little more than the presumption that several sources

of pleasurable stimulation are somehow related to one another. Freud first applied the properties of adult genital sexuality to infantile activities centered around the oral and anal-urethral body zones and then assumed that there was a specific quantum of pleasure-seeking that could be channelized through these various zones, making one substitute for another. The evidence cited here supports the general correctness of the first point, but throws less light on the latter." The existence of something resembling the "polymorphous perverse" disposition is corroborated, but the claimed prevalence of a castration complex, and the claim that all children are unable to accept anatomical sex differences without emotional shock, are not corroborated.

Progression of Object Choices. Freud described a progression of object choices which he considered universal in the development of human beings. The first of these, during the autocrotic phase of infancy, is self-love or narcissism. The second is mother love. Thirdly, comes the attachment to the parent of the opposite sex termed the Oedipus complex, which is broken by threats of castration. Fourth, comes the latent period during which libidinal objects are absent as a result of the repression of the Oedipus. Finally comes the fifth stage, beginning at puberty, when heterosexual objects outside the family are chosen.

Freud's first two stages of object choice are probably typical. The newborn child is narcissistic in the sense that gratifying it requires that its basic drive stimuli must be reduced. The results of the laboratory studies related to cathexis coupled with the fact that helpless infants must depend upon sociological mothers for reduction of their biological drives would lead one to expect that these mothers should be the first love objects. Such expectations are confirmed by studies of social responsiveness in infants. These studies have shown that at some time during the first three months, the sound and sight of mothers serve to stop crying (see Ribble, 1944, and also the developmental studies by Buhler and by Gesell). The specificity of the mother choice, however, is to be questioned. It should depend on the discriminative capacity of the child and whether one or several sociological mothers participated in its gratification. Whether this choice of the mother leads to an

actual genital love response is still more questionable, but objective data are lacking.

On theoretical grounds, Freud's claim that the Oedipus situation or preference for the cross-sexed parent is universal in human development would appear to be gross overgeneralization. The complex of intrafamily relationships described by Hamilton's American subjects and the variety of family relationships described by anthropologists shows that the required degree of consistency in family constellations does not exist. Furthermore, studies of parental preferences by Terman and by Stogdill show insignificant differences between those of boys and girls. Stott has found that children on the average criticize both parents equally, but that girls, perhaps because they tend to be more articulate, are more critical than boys. Moreover, a study by Bell has shown that strong emotional attachments outside the family are common even in early childhood. In combination these considerations argue that the Oedipus situation cannot have the importance as an archetype for all future love relations that Freud attributed to it. This is not to deny its existence, nor to deny that the affective attachments of children within the family are important. The studies so ably surveyed by Symonds (1939) confirm Freud's emphasis on the importance of the family, but not on the particular pattern described as the Oedipus situation. It should be mentioned that in much of recent psychoanalytic literature a less literal conception of the Oedipus is employed than Freud described.

Freud's claim of a universal absence of personal love objects during the latent period as a result of the repression of the Oedipus is also an overgeneralization. It is contradicted by the relative frequency of romantic attachments and heterosexual play during this period reported in the studies by Davis, by Hamilton, and in those surveyed by Willoughby. On the other hand, common observation and a study by Bell have shown that shyness and avoidance of the society of members of the opposite sex in informal situations is very common during the latent period, the gang age. Whether this is due to repression of the Oedipus or to other factors in socialization is not to be determined by these studies in our culture, but the patterns of sex behavior described by Mead in her studies of

sex and temperament in primitive societies argue in favor of the other factors in socialization. The rise of heterosexual love objects after adolescence is, of course, well-substantiated.

The Effects of Infantile Experience. In the dynamic life process, psychoanalytic theory assumes and psychoanalytic evidence indicates that the infantile experiences associated with feeding, toilet training, genital behavior, and the social conflicts within the family set up behavior trends which influence adult behavior. Studies of the relation between the common temperamental characteristics of various primitive groups and the kinds of infantile experience to which the individuals in these groups are typically submitted have tended to confirm this general contention (see summary of the evidence in Ch. 6 of Money-Kyrle, 1939). In the sense that free feeding and late weaning is commonly associated with generosity and optimism, and that oral deprivation and early weaning is associated with stinginess and greed, these anthropological studies tend to confirm Freud's contentions. Such evidence has suggested to Hunt (1941) that indirect tests of this hypothesis could be made by the experimental control of the life history of animals. In one study of this sort, he found that rats submitted to a frustrating feeding schedule in infancy, where time of eating and time between feedings was controlled, hoarded in adulthood nearly three times as many pellets of food as their litter-mate controls allowed free-feeding. This was true for two litters in which the feeding schedule began when the animals were 24 days old, but the same feeding schedule begun when the animals in two other litters were 32 days old did not affect the adult hoarding. Repetitions of this experiment have confirmed the effect, but they have not produced such large differences as that found in the first. Although rats are certainly different from human beings, this experiment lends support to the psychoanalytic contention that the effects of infantile experiences may last and influence adult behavior. The fact that feeding-frustration is not sucking frustration allows the experiment to say nothing about carry-over of the effects of the latter. On the other hand, it argues that the frustration of other drives than those included in Freud's conception of the libido may be important for adult behavior.

For theoretical interpretation of his results, Hunt turned to the principles of learning theory. Assuming that the infantile feeding frustrations produced an autonomic response akin to anxiety, he argued that a little hunger in adult animals with a history of feeding frustration might serve as a conditioned stimulus for this autonomic response. Thus, although such animals enter the hoarding tests with the same strength of hunger drive as their litter-mate controls with a history of free feeding, they have in addition the anxiety drive. Such a theory differs sharply from libido theory in the sense that it makes the autonomic responses or anxiety the key to the effects on adult behavior. The importance of anxiety for neurosis was clearly recognized by Freud (1936), but its chief basis he put in the repression of libidinal drives, and later in the repression of the death instinct, and attributed to these more central significance than they deserve theoretically.

Experimental Origins of Traits and Symptoms. Studies which attempt to recover factors of the life history in interview or questionnaire, although they are inferior to psychoanalytic studies in their completeness concerning dynamic details, afford a statistical check on the generalizations from psychoanalytic studies of individual patients concerning the experiential origins of trait constellations because they start with a broader sample of the population and/or utilize control groups. In general the data from such studies, where relevant, have tended to lend support to psychoanalytic contentions. In his study of marriage, Hamilton found a larger percentage of those subjects who recalled anal eroticism showing such anal erotic traits as stinginess and sadism than were shown by subjects who recalled no anal eroticism. Paranoid patients show a higher percentage of homosexuality, symbolic, overt or measured as femininity on the Terman-Miles scale, than do patients in other diagnostic groups or than do normal individuals. This would be required by Freud's notion that the projection in paranoia is the end product of a series of attempted defenses against homosexual urges. The fact that the surveys by Hamilton and by Terman have found no association of such factors as childhood sex aggressions or shock, goodness of sex instruction, and early attachments to and con-

flicts with parents with orgasm inadequacy in women fails to support the psychoanalytic hypothesis that the inhibition of sexuality results commonly from fears during childhood. On the other hand, the fact that Hamilton found orgasm inadequacy slightly more common among women who continue masturbation after marriage than among women who do not may lend some support to infantile fixation of sexuality on the clitoris as a factor in hyposexuality. The reasoning here assumes fixation to mean a strong habit, and the persistence of a habit is one measure of its strength. Taken together, the various studies of sex-factors in the life history have shown that any deviation from standard heterosexual behavior tends to be associated with higher than average incidence of all the other deviations. This fact lends support to the view that there is a correlation among all perverted impulses (Freud, 1905, p. 571). The fact that Hamilton found the orgasm capacity of women showing any of the perverse tendencies to be lower than average also lends indirect support to the psychoanalytic hypothesis that hypersexuality is often an attempt to discharge nongenital tensions (Fenichel, 1934, p. 281 ff.). This hypothesis is further strengthened by the obverse fact that women selected for high copulatory frequency in marriage tend to have a history of affectionate family life and early indications of strong heterosexual drive as shown by frequent "petting," a higher than average incidence of intercourse with their husbands and with others before marriage. Such confirmation consists only of statistical trends, but when it is considered that such statistical surveys must miss the dynamic relations among and the relative strengths of the forces with which psychoanalytic theory is concerned, only statistical trends could be expected. Only when objective control of the dynamics of the life history has been accomplished can one expect to test the details of psychoanalytic hypotheses about such sources of symptoms. Until then the psychoanalytic method remains as an important exploratory source of such information.

DESCRIPTIONS OF PERSONALITY STRUCTURE

The basic psychoanalytic description of personality structure as id, ego, and superego is not open to experimental attack, for it consists logically of a classification of behavioral trends

in terms of their sources. On the other hand, the descriptive accounts of patterns of adult characteristics derived from continuations of, sublimations of, and reaction formations against the behavioral tendencies resulting from fixation of the libido at various stages (Brown, 1940, p. 206) might be examined with correlational methods. In one such study of this sort, Sears has shown that the correlations among ratings of stinginess, obstinacy, and orderliness in a group of college men are all positive and in the direction predicted by the theory of an anal character type. Experiments employing the method of factor analysis might be designed to test other trait constellations described in the psychoanalytic literature.

FIXATION AND REGRESSION

In his psychoanalytic practice where the perspective of the whole life history is available, Freud found that certain individuals pass through the stages of psychosexual development, and then develop neuroses the symptoms of which represent a reversion to earlier stages of development. Such regression occurs when the libidinal gratification of the individual is frustrated. The object or stage to which the individual returns is determined by the "tenacity with which the libido holds to particular objects or to particular channels." This tenacity, the second factor in regression, Freud called *fixation*, and he confessed his ignorance of its causes.

Fixation. In the laboratory it has been customary to isolate processes for investigation. From the laboratory experiments in animal learning, which have been done quite independently of psychoanalysis, comes considerable information relevant to psychoanalytic process of fixation. The studies, however, have for the most part been concerned with different aspects of a behavior process than Freud considered. In any behavior sequence, one can distinguish (1) the drive, (2) the goal response which reduces the drive, (3) the object necessary for performance of the goal response, and (4) the specific instrumental acts enabling the organism to reach the goal object. While Freud talked of the tenacity or strength of object choices and libidinal channels, the laboratory studies have considered object choices only a little and libidinal

channels not at all. Experimental studies have been concerned primarily with the fixation or reinforcement of instrumental acts.

Freud suggested that attachment to or love of objects, that is, their cathexis, results from gratification of libidinal needs by an external object or person. In this connection, various studies by Mierke, by Rosensweig, and by Nowlis have shown that object preferences of children can be changed by experiences of success and failure in connection with their use. K. A. Williams has shown that feeding rats in a white food box gave it acquired reward value. The rate at which the rats were learning a maze without food reward picked up sharply when the white food box in which they had previously been fed was substituted for an unpainted redwood box in which they had never been fed. S. B. Williams (1934) has shown that rats required more trials for the extinction of a maze habit when they were allowed to enter the food-box in which they ate during training than they required when they were kept out of the food-box. Razran has shown that playing modern music while adult human beings are eating a free meal increases their preferences for it, and that similar results are obtained with photographs of faces. Several other studies have shown that object choices may be acquired through the type of generalization termed identification in psychoanalysis. Duncker, for instance, has reversed the food preferences of children by reading them an animal story in which the hero, a mouse, had liked the unpreferred food. Thurstone has increased the favorableness of attitude toward Chinese and Germans in children by showing them dramatic movies in which people of these nationalities appeared as heroes. Such studies confirm Freud's general conception of the role of gratification in the formation of object choices or in cathexis, but they also indicate that gratification of other than libidinal needs can serve to produce cathexis. They say little about the all-important factors controlling the strength of object choices. Wolfe has shown that increasing the number of grapes given for red chips led the animals to choose red chips instead of white in a free-choice situation, a fact indicating that the strength of the attachment to an object is a function of the amount of primary reward associated with it. Except for this illustrative

example, the factors controlling the strength of object fixation remain unknown.

Experiments in animal learning have uncovered a number of factors controlling the strength of instrumental acts, where strength means resistance to change as it does in the clinical situation. (1) It has been shown that the more trials of practice or reinforcement rats get in a given instrumental act like turning at a given point in a maze or pressing a bar to get food, the more trials required to get them to make a different turn or the more trials required to extinguish the bar-pressing act. (2) With the number of trials held constant, the stronger the drive at the time of learning an act like bar-pressing to get food, the more trials required to extinguish the act. (3) Accuracy of a delayed response is reduced by relatively small differences in the amount of food given to chimpanzees, and this is probably a factor in the fixation of habits. (4) The longer the interval between the time a rat presses a bar and the time it gets food, the fewer the number of trials required to extinguish the act. (5) When a puff of air is given every other trial in conditioning the eyelid reflex, the number of trials required for extinction is larger than it is when a puff is given every trial. Similarly, if rats are given food only every other time they run down a runway to a food box, more trials are required for extinction than are required when they are fed every trial. (6) When such punishing stimulation as shock is given as rats are in the process of turning one of two directions at the choice point in a maze, the choice taken requires more trials for extinction than is required by one not so punished. (7) When stimuli associated with reward in the learning process are present during extinction, more trials are required for extinction than are required without the presence of these stimuli. (8) In the case of relatively brief intervals of a few days, extinction has been shown to require more trials if time is allowed to elapse between the learning and the extinction processes. Although the studies of animal learning were not stimulated by psychoanalytic theory, they clearly have considerable to say about the factors controlling the strength of fixation.

Regression. Freud distinguished between two different types of regression: *object regression*

in which the individual reverts to an earlier object choice and a "return of the entire sexual organization to an earlier stage of development" which has been called *drive regression*. Neither of these forms of regression has been studied experimentally, but a third type of regression, in which the subject reverts to a previous instrumental act (*instrumental-act regression*), has been experimentally investigated, and so has a fourth type which may be called the *primitivation of action*.

The relation between fixation and regression has been clarified considerably by the animal experiments on instrumental-act regression. Hamilton and Krechevsky apparently made the first of these experiments. They trained rats to choose the shorter of two alleys in a single-unit T-maze, then reversed the sides of these two alleys and started retraining. When shock was applied to the rats of the experimental group at the choice point after the retraining had got well underway, nearly half of the animals promptly reverted to turning in the previously learned direction even though the distance to food was longer. A control group simply learned the new habit. Although these investigators interpreted this as regression to a previously learned habit, the fact that not all animals regressed suggested that it might have been simply reversion to an "innate preference" of direction. An experiment by Saunders showed that if rats are first trained to take their preferred direction of turn, a higher percentage of them will regress, and regress more readily, when shock is applied at the choice point after learning in the opposite direction is well underway. Saunders interpreted these results to indicate that regression occurs only to acts with an innate basis, but they may also indicate simply that the extra strength of the first learned direction derived from the "innate" directional tendency of the rats determined the readiness with which they regressed. Evidence for the latter interpretation comes from an experiment by Martin, who, using a similar apparatus, found that the proportion of rats regressing was a function of the amount of training given for the first direction of turn. Experiments by O'Kelly with different apparatus have confirmed Martin's results.

When Saunders shocked animals outside the

T-maze, regression to the first trained direction of turn did not occur. Mowrer has suggested that this is due to the fact that the shock was not applied so as to reduce the strength of the last-learned habit. He trained one group of rats to escape electric shock on a floor-grill by standing on their hind legs. Then he retrained them to escape shock on the floor by pressing a lever at one end of the experimental box. A control group was trained only in the latter habit. When he then frustrated the lever-pressing act by electrifying the lever, all those trained to stand on their hind legs reverted to this form of escape while only one of the five not so trained reverted. This experiment demonstrated that the frustrating circumstances must serve to reduce the strength of the last-learned habit and that regression can occur to a response which is not originally dominant.

Removal of reward has also been effective as a frustrating agent to produce regression. Hull has trained rats to run down an alley for food first in a 20-foot alley and then in a 40-foot alley. In such a situation, rats exhibit a gradient in the rate of running. They start slow, speed up, and then slow down again near the food box. When the animals trained first in a 20-foot alley were learning to run down the longer alley, they slowed down 20 feet from the starting box. This hump in the speed gradient disappeared with training, but it reappeared when, during early extinction trials, no food was given. Using a similar method, Miller and Miles have found a regression to the hump gradient in rats from an administration of alcohol. Moreover, O'Kelly has found that rats will regress to an earlier habit if they are tested after satiation.

These experiments amplify the psychoanalytic conception of regression considerably. They indicate, at least so far as instrumental-act regression is concerned and probably for other forms as well, that regression is primarily a function of the strength of previously fixated behavior tendencies when the current one is weakened. It may be weakened by making it painful (shock), by removing its rewarding character, by the action of drugs, or even by satiation. By analogy, it would appear that having a childish habit which is excessively strong is pathologically predisposing. This is the gist

of Freud's interpretation of the psychoanalytic data relative to regression. By virtue of their long maturation, children must learn and then give up many object choices and instrumental acts before they are socialized adults. How to effect habit progression and the relinquishment of old habits without predisposing children to regressive pathology is one major social problem. What are the laws of hierarchical learning? These animal experiments are merely a beginning, but Mowrer and Kluckhohn (1944, pp. 96-131) have amplified the psychoanalytic story by considering this problem theoretically in terms of the variables (amount of reward, amount of delay, amount of effort, and the amount of danger of discomfort) controlled in experiments on animal learning.

Primitivation of action has also been demonstrated as a consequence of frustration in an experiment with children by Barker, Dembo and Lewin. A scale of constructiveness in play was constructed which yielded a "play age" in monthly units. Then a group of 30 nursery children were individually observed at play through a one-way screen to ascertain as a control their degrees of constructiveness. On a later experimental day, each of these children was shown a new set of toys in the experimental room. He was allowed to play with them for 15 minutes. Then, without explanation, he was led to the other end of the room where he had played on the day of the control-tests, and a wire screen was pulled down in front of the new toys. The child was then observed while he played for 30 minutes with the old toys, and the constructiveness of his play was rated. The resulting decrement in play age averaged 17.3 months, a relatively severe regression in children whose age ranged between 29 and 61 months. Individual differences were considerable, and the amounts of primitivation were positively related to the intensity of the signs of frustration. The fact that one of the children actually exhibited a higher play age after the frustration than before raises an interesting question. What are the variables in the life history of children which control their reactions to such frustrating experiences? This experiment, while it does not isolate these variables, has the value of pointing to their existence and to the incompleteness of present-day learning theory.

The schizophrenias have commonly been considered regressive disorders where the individual has reverted to one of the pregenital stages of psychosexual organization. As an indirect attack upon this interpretation DuBois and Forbes have observed the postures of catatonic patients during sleep. Only nine per cent of the patient's postures were of the predicted foetal variety; and only six per cent of their total sleeping time was spent in these postures. A single normal control subject yielded similar figures. In another indirect attack upon this interpretation, Cameron has compared the frequency of the ways schizophrenic patients complete "because" sentences (e.g., A man fell down in the road because . . .) with the frequency of the ways Piaget had found that children complete such sentences. While Piaget's children exhibited a maximum percentage (83.5) of explanations in terms of *motivation* (e.g., because he wanted to), a minimum percentage (7.5) of explanations in terms of *cause and effect* (e.g., because he stumbled), and an intermediate percentage (9.0) in terms of *logical justification*. Cameron's schizophrenics gave only 32% of explanations in terms of motivation, a maximum (45%) in terms of cause and effect, and a minimum (23%) in terms of logical justification. The sleeping postures and the thought forms of schizophrenics considered here do not confirm the regressive conception of schizophrenia, but these are but two of the many factors in schizophrenic behavior and they are not the drive factor central for psychoanalytic theory. There is considerable experimental evidence that schizophrenics suffer a loss of their acquired drives (Hunt & Cofer, 1944, pp. 1001-1005), but this evidence is also but loosely related to the psychoanalytic theory of schizophrenia.

AGGRESSION

Before Freud formulated his conception of a death wish in his metapsychology (*Beyond the Pleasure Principle*), he had described the native reaction to a frustration of pleasure-seeking as a feeling of hostility toward or an aggressive attack upon the source of frustration (*Mourning and Melancholia*). A reformulation of this simple statement of the relation of aggression to frustration in terms of its quantitative-aspects principles have recently been described by

Dollard, *et al.* (1939). (See *Frustration and Aggression*, this volume.)

THE DYNAMISMS

Because the theory of the psychoanalytic dynamisms permits experimental isolation, they have invited a number of such tests. Basic among these is *repression* whereby an individual defends himself against unwelcome impulses or the anxiety resulting from the arousal of these impulses. The other dynamisms (e.g., reaction-formation, the substitute-formations, and projection) are primarily supplements to repression.

Repression. Objective studies of repression have been concerned with infantile amnesia, the effect of unpleasantness on memory, the measurement of existing repressions, the experimental production of repression, and with testing the psychoanalytic generalizations about the influences of unconscious processes.

Freud considered that the inability to recall infantile experiences was a function of the disapproval with which the expression of pre-genital and genital impulses had been met in the early years. This disapproval served to make such impulses into stimuli for anxiety reactions. One of the ways to avoid the anxiety is to inhibit or repress the impulse, an automatic process, which Freud (1915) termed *primal repression*. Because any memories or ideas associated with the inhibited impulse would tend to arouse the anxiety, noticing them or becoming conscious of them would also be inhibited (*after expulsion or repression proper*). Freud considered this process general or universal. Studies by the Dudychas have shown, however, that recall of incidents from the third to the fifth year of life is common for most adolescents and adults for infantile sexuality. Moreover, many of the 200 adult subjects in Hamilton's study of marriage recalled even sexual experiences from early childhood. Although they say nothing about Freud's theory of repression, such studies argue against the universality of infantile amnesia. Freud was apparently impressed by the apparent vividness of the early experiences of children and he assumed that childhood events should be as well impressed as later ones. Studies of the learning ability in children, however, have shown clearly that the efficiency of memorizing during infancy is relatively poor.

Studies assuming a quantitative relationship between amount of repression and amount of neuroticism have yielded contradictory results. Crook and Harden found that neuroticism, as measured by the Presley X-O test, correlated $-.37$ with the number of infantile memories given by college students and $-.52$ with the age given for the first recalled experience. When Child repeated this study using several neurotic inventories, he found no such correlations. He also pointed out that the assumption of a positive relationship between amount of amnesia and amount of neuroticism violates Freud's contention that neurosis represents a failure of repression.

Because Freud wrote frequently about forgetting the unpleasant, many experiments attempting to test this hypothesis have simply correlated ratings of the pleasantness of items with the efficiency of their recall. Due to the fact that the unpleasantness about which Freud spoke was the anxiety specifically connected with the arousal of a previously punished impulse, these studies, as Sears (1936) has pointed out, are irrelevant to repression theory. Somewhat more relevant are the studies in which subjects have been asked to recall their real life experiences during a stated interval and then rate these as pleasant or unpleasant. In four or five of these studies, a majority of the recalled experiences have been rated as pleasant. To refine the measure of recall, Stagner had his subject write out a list of odors, objects, and feelings associated with each of the experiences described. When, three weeks later, he asked for recall of these associated items, recall clearly favored the pleasant experiences.

Sharp and also Flangan have designed an ingenious measure of real life repressions which consists of comparing the learning and retention of nonsense syllables paired to yield profane ("jeh-sus," "dam-mir") or sexual ("tew-bal," "piy-nis") meanings with others paired to yield neutral meanings. In both experiments the learning occurred with fewer trials and recall was better after 24 hours for the control than for the experimental lists. These results constitute an experimental confirmation of Freud's hypothesis of after-expulsion or repression of items associated with previously punished impulses. In an extension of this method, Sharp secured from the case histories of a group of neurotic patients lists of 15 words referring

specifically to the sources of their anxieties and another list related to their gratifications. When these words were arranged into lists of paired associates (e.g., "feeling-inferior," "going-insane") both this group of patients and a control group of neurotics showed approximately the same number of trials for learning but significantly worse recall for this experimental list than for a control list. The fact that Sharp also got similar results from a group of normal adults suggested to Heathers and Sears that the experimental pairs were tapping sources of repression fairly common in people with an American background. When they attempted to reproduce Sharp's results with normal adults and college students, however, they failed.

Freud's theory of repression, like nearly all of his hypotheses, constitutes an interpretation after the fact. The psychoanalytic method allows little opportunity to test the hypothesis predictively. Several investigators have attempted to test the theory by way of producing repression experimentally. In what is probably the first of these, Rosenzweig and Mason arbitrarily made children individually complete half and fail to complete half a series of simple jigsaw puzzles. In an attempt to produce anxiety for those failed, each child was told that he had "failed the test." When the series had been finished, the child was asked to recall the names of the puzzles he had tried. Although Zeigarnik had shown a tendency to recall more of the uncompleted tasks, in this situation the children recalled a greater percentage of the completed tasks. The fact that the discrepancy was largest for those children rated high on "pride" suggested that the anxiety involved in the experience of failure accounted for this discrepancy in recall. In a subsequent study with college students, Rosenzweig got further confirmation for this interpretation. He presented some puzzles to one group with the explanation that he was testing their intelligence, and the same puzzles to another group with the explanation that he was seeking information concerning the relative difficulty of the various puzzles. The former group, where pride or the ego was involved in completing the puzzles, recalled more of the completed puzzles; whereas the other group recalled more of the uncompleted puzzles. McGranahan has compared the number of color words given as associations to a list of words by a group of college students

without instructions and by another group who were instructed not to give color names and were threatened with shock if they did. The latter group averaged fewer and showed greater variability than the former in the number of color names given, and the numbers given by individuals were correlated with their resistance to the effects of shock. When Sears and Virshup repeated this study with three groups, they found that both instructions to inhibit color names and shock reduced the number of color associations, but they did not find increased individual differences as a result of the shock. These studies tend to confirm Freud's hypothesis, but as yet they have not provided a method to approach the quantitative problems which Sears (1936) has found explicit and implicit in Freud's theory of repression.

Hypnosis has been used as a way of inducing unconscious processes to test their effects. Luria has induced unconscious conflicts hypnotically and shown that they affect muscle tension and the time and content of word-associations. Huston, Shakow, and Erickson have described effects of hypnotically induced conflicts on social behavior, both verbal and gestural. They have stipulated that these influences are obtained only when the subject exhibits amnesia for the period when the "complex" was induced. Erickson has shown that unconscious conflicts hypnotically induced can alter the content of conversation, produce conflict about smoking, verbal slips and other phenomena like those described by Freud in *The psychopathology of everyday life*.

The conditioning technique has been employed to test Freud's claim that unconscious tendencies are less modifiable than those of which a subject is aware. Baker and Metzner (1939) have reported conditioning the galvanic skin response (GSR) to the sound of a buzzer of which his subjects were unaware because of their instructed concern over the threat of being given a hypodermic injection. When the subjects were shown that they had never been given the injection and the buzzer was called to their attention, seven of the 15 were immediately extinguished. In another experiment, Haggard (1943) has shown that the more his subjects knew about the conditions of the situation in which he conditioned the GSR to a stimulus word with electric shock, the less autonomic reactivity they exhibited and the

more rapidly the GSR could be extinguished. Both the hypnotic studies and those employing the conditioning method tend to confirm the psychoanalytic contention that unconscious impulses have influence and are less easily modified than impulses of which a subject is aware.

REACTION-FORMATION

Reaction-formation, or the tendency to exaggerate the converse of a repressed impulse, has received little experimental attention. In his study of regression, however, Mowrer observed a tendency analogous to reaction-formation in rats. The animals had been trained to press a lever at one end of the experimental box to avoid shock on the wire grill which floored the box. Then, when the learning of this habit had reached criterion, the escape lever was also electrified. On each trial the floor shock was weak at first and increased gradually in intensity. After the animals had experienced shock on the escape lever, the first perception of the weak but gradually increasing floor-shock instigated movement away from the escape lever. When the floor-shock had increased in intensity, the animals returned to press the electrified escape lever. Mowrer interpreted this moving away from the lever as indicating that reaction-formation is a type of response dictated by the relative strength of the anxiety or stimulation from two sources at the time it occurs.

SUBSTITUTE-FORMATIONS

Freud (1915) pointed out that the repression of punished impulses may be maintained by displacement in which some substitute gratification is accepted. Displacement may also occur in response to external frustration. The experimental work on substitution, like that on regression, has involved a different aspect of behavior than that to which Freud applied the concept. The original work of Ovsiankina, which has served as the model, measured the effects of interpolated substitute tasks on the tendency to resume interrupted tasks. With this method she attempted to determine the factors which, on the average, make one task a good substitute for another. In summarizing the results of such studies, H. H. Nowlis has pointed out that the effects of the interpolated substitute tasks on the strength of the tendency to resume the frustrated tasks is a function of

(1) the degree of similarity between the interrupted task and the interpolated substitute, (2) the degree of difficulty of the substitute task relative to the one interrupted, (3) the degree of contact between the tension systems involved in the two tasks, and (4) the degree of reality of the substitute task. Such results amplify the psychoanalytic concept more than they confirm it. Nowlis has also shown that the tendency to resume a frustrated activity is increased when feelings of success are induced in connection with the substitute task, a finding with interesting implications for therapy.

Miller has done experiments relating Freud's concept of displacement to generalization in conditioning. In one of these, rats were made to fight by electrifying the grill which floored the experimental box. When only one rat was left in the box with a glass bottle covered with adhesive tape, electrifying the floor-grill induced him to box the bottle as he had boxed the other rat. A theoretical statement of quantitative laws governing such generalization or displacement which amplify the psychoanalytic conception appear in *Frustration and Aggression* (Dollard, *et al.*, 1939). A theory of response-produced generalization has been given by Miller and Dollard (1941). The approach to generalization by way of semantic conditioning has provided an experimental approach to the associative effects of suppression and repression (Cofer and Foley, 1942).

A special form of substitution is sublimation. Freud assumed that repressed pregenital drives and occasionally genital drives may be transformed into motives which have higher cultural value. In an attempt to test this hypothesis, Taylor has found that all of a group of 40 young unmarried men, who because of their intellectual attainments and esthetic refinement might have been expected to exemplify a high degree of sublimation, habitually obtained direct genital gratification. It is doubtful, however, that this constitutes a test of Freud's theory of sublimation. Taylor's assumption of a negative correlation between intellectual activity and genital activity need not follow from Freud's theory of sublimation. In fact, Freud remarked frequently about the persistence of genital impulses. On the other hand, it is a real question whether the transformations in development involve the basic drives as Freud's theory assumed. A better theory appears to be that of

acquired drives (Mowrer and Kluckhohn, 1944; Miller and Dollard, 1941).

PROJECTION

Although Freud failed to define projection adequately, he (1911) interpreted it as a defense mechanism whereby the anxiety aroused by impulses threatening to escape their repression is externalized so that the individual may partially reduce it by seeing himself as blameless or victimized, or control it by avoiding the situations which tend to arouse the incompletely repressed impulses (phobias). In an experiment designed to measure already existing behavior of this sort, Sears had college fraternity men rate themselves and each other on stinginess, obstinacy, disorderliness, and bashfulness. Those men who were rated excessively high in these traits and who also lacked insight, as shown by the fact that their self-ratings deviated markedly from the average of the ratings given them by the group, attributed more than the average amounts of these traits to others. In other words, projection as indicated by the attribution of traits is a function of lack of insight which Sears considered analogous with repression. One might assume the source of such repression to be the guilt for possessing an undesirable trait, but against this assumption was the fact that he found such projection occurring for the desirable ends of the trait-continua as well as the undesirable; for instance, for generosity as well as for stinginess. Wright, on the other hand, has created the conditions of guilt, theoretically considered necessary for projection, and found that projection does occur much more frequently when these conditions are fulfilled. In this experiment, eight-year-old children were individually given a preferred toy and an unpreferred toy to play with. Each of the children in the experimental group was then put in a conflict situation by being asked to give one of the toys to a friend. After this he was asked which toy the friend would have given him. Those in the experimental group who had given away the unpreferred toy, for which presumably they felt guilty, said the friend would have given them the unpreferred toy very much more frequently than did a control group of children who had not been submitted to the conflict situation.

Hunt has observed something akin to projection in rats. The animals had been kept in

more or less continual drive conflict by electrifying their water supply. In test situations, Hunt offered these animals another drinking tube from which they had never been shocked. While they were pursuing this tube, he led the animals to the one from which they had always received shock, but during the tests the shock was disconnected. In several instances, rats drank for a period from the tube from which they had been shocked and then jumped briskly away shaking their noses as if they had felt shock. The behavior implied a hallucination of shock. Whether this behavior constituted more than a conditioned response with sensory components is dubious, however, for it is difficult to see how it constituted a defense mechanism. It resembles more the motivated perception of the projective methods. In this connection, Sanford has found that the frequency with which food items are mentioned in the thematic apperception of pictures is roughly a function of the degree of hunger.

Ideas of reference constitute a special form of projection in which it has been contended that feelings of self-criticism are externalized. Experimental evidence for this contention exists. From his blindfolded subjects' introspections, Coover concluded that the belief that they could tell when they were being stared at came chiefly from attributing objective reality to such subjective impressions as a "feeling of nearness to the experimenter" and a "feeling of being criticized." In a questionnaire study, with college men, Sears has found a correlation of $+0.82$ between his measures of their ideas of reference and their feelings of self-criticism.

DREAMS

Freud began his study of dreams because his patients spontaneously brought them into their discussions with him. Many parts of Freud's theory of dreams have been attacked with verbal criticism, but few have received experimental attention. A majority of the experimental work on dreams has been concerned with the effects of external stimulation and the results are of little import for Freud's theory. On the other hand, studies by Cason and by Malamud and Linder have shown that personal problems participate in determining the content of dreams. Freud's theory of universal dream

symbols has been widely criticized, and two investigators, Schrotter and Roffenstein, have attempted to study the problem of symbol formation experimentally by suggesting to a subject while under hypnosis that he would dream about topics where repression was presumed to be in operation. Both Schrotter and Roffenstein obtained dreams by this method wherein symbols similar to those described by Freud occurred (see White, 1944).

CONCLUSION

A majority of the descriptive and theoretical psychoanalytic propositions to which there exists relevant objective or experimental evidence have received some support from this evidence. Notable descriptive exceptions, however, are the generalizations (1) that the Oedipus complex is a universal or even a majority pattern in human development and (2) that the castration complex, strictly defined, is as common or has the power to produce repression that Freud considered it to have. A notable theoretical exception is the proposition that the gratification of libidinal drives alone accounts for emotional attachments to objects or persons. The objective evidence and learning theory both argue that the course of human development involves a broader drive basis and is much more variable than Freud's description of it would imply.

Experimental studies have usually lent support to Freud's conceptions of the dynamisms, but the experiments instigated directly by psychoanalytic theory have discovered no new behavioral principles. On the other hand, the independent evidence from the experimental psychology of learning has amplified considerably the Freudian conceptions of fixation and substitution. Moreover, through this amplification of the conception of fixation, this experimental evidence has added considerably to knowledge of the process of regression, and in the future it promises to produce a body of demonstrated quantitative facts concerned with conflict within the individual.

EXPERIMENTAL PSYCHOLOGY.—

Definition. There are several interpretations that may be given to the term "experimental psychology," according as the emphasis is placed upon method, procedure or subject matter. Generally speaking, experimental psychology refers to the study of psychology conducted in a scientific fashion, where the emphasis is upon the objective and controlled determination of the stimulus response relationship in behavior. The term is often applied to the type of psychology whose methods and viewpoints are opposed to the subjective and philosophical; in this sense, experimental psychology differs from rational psychology which is a branch of philosophy.

More specifically experimental psychology refers to the procedures by which facts relating to behavior are obtained. When the stimulating conditions are controlled at least in part, when the variables are isolated for purposes of study, where instruments are used for more precise stimulation or more accurate recording of the responses, where the data are expressed in numbers to which statistical computations may be applied—then the findings are looked upon as being experimental, and are generally woven into some theoretical framework without concern as to their practical applications, as is done in applied psychology. Naturally these procedures may be and are applied to nearly all fields of psychology, often with great ingenuity and skill, and in this sense these psychologies are experimental.

Most precisely, however, the term "experimental psychology" is limited to the scientific study of the normal human adult, particularly in the fields known as sensation and perception, feeling and emotion, attention, memory and learning, thought and the higher mental processes, motor phenomena, and kindred topics. On the other hand, the divisions of psychology which are called genetic, abnormal, social and comparative psychology, etc., are not included

in experimental psychology, because, while their procedures may be truly scientific, they do not have as the object of their study the normal adult human.

This characteristic of experimental psychology which differentiates it from other fields of psychology has been aptly brought out by Dashiell in his presidential address to the American Psychological Association in 1938, wherein he stated:

"In high contrast to the experiment is what I am taking the liberty of calling 'the clinical method.' I use the name—for want of a better—to include all those procedures in which the peculiar make-up of the individual person is the primary subject matter, and in which his particular career is considered on its own account. . . . But we must bring into sharper focus the differences between the experimental and the clinical approach to the study of man. In the former the aim is to analyze the specific contingent relationships, and . . . to hold constant or negligible all other variables than the one or two that form our particular concern. By definition, almost, experimentation assumes the isolation of a phenomenon from all incidental and simultaneous cross-phenomena. We study such things as the various factors that modify a *typical* human being's reaction time, or the relationship of time interval to loss of ability to reproduce a memorized passage by adults *in general*, or the dependence of the variable of problem-solving ability upon the age variable in the *average* child. Note two things: (a) we do not isolate the individual person *qua* individual; but (b) we do isolate the particular function or phenomenon in question. Quite to the contrary, when we make a clinical approach to the study of John Doe, (a) we are interested in John Doe not as a specimen but as a unique thing; to be considered *sui generis*, whose past, present and future may be our prime concern; and (b) we are interested in him *in toto* and in his natural and social habitat."

Accordingly the following definition of experimental psychology is proposed: The study under controlled conditions of the behavior of the normal human adult, in an attempt at a

dimensional analysis of the relationship between his internal and external stimuli and his resultant responses. The emphasis, however, must be placed upon the content rather than the procedure, for the traditional fields of investigation of experimental psychology are fairly well defined.

THE MAIN FIELDS OF INVESTIGATION

Oftentimes renewed interest in psychology has originated from cognate sciences, from physiology, physics, biology or medicine. As a consequence no sharp line of demarcation can always be drawn between experimental work that is psychological or that which is physiological, for instance. In other terms, the mode of approach and not necessarily the broad content of a field determines whether work can be classified as belonging to one or other of the major scientific disciplines. When the purpose of an investigation is concerned with the functioning of an individual and his modes of response to varied stimuli, we are concerned with experimental psychology. More and more, as the border lines of certain sciences become tenuous, what may properly be called psychology or physics or physiology is harder to determine, for the factual treasure-house, the techniques, and the hypotheses are often mutually dependent.

Even in the field of psychology itself, one may not always distinguish between experimental psychology, comparative psychology, etc. The lines are not always clear cut, for not only do these branches use the experimental approach but often their fields tend to coalesce. Some division, however artificial, may be made, and one may follow in general the classification scheme of the Psychological Abstracts, and somewhat arbitrarily break up the fields of experimental psychology as follows:

The receptor processes and sensation.
 Perception, discrimination and psychophysics.
 Motor responses, work, fatigue.
 Glandular responses and emotions.
 Electrical phenomena of the body.
 Motivation and voluntary processes.
 Learning and conditioning.

Higher mental processes—attention, aesthetics and thought processes.

The division is not a satisfactory one, for many rather fertile fields of investigation, e.g., attitudes, would have to be located in one of the above groups only by an extension of the ordinary meaning of the terms. It has the merit, however, of forming the basis upon which articles are divided in the current classification of psychological literature and of specifying what comes under the head of experimental psychology.

PROCEDURES AND METHODOLOGY

Ward stated in his article on psychology in the *Encyclopedia Britannica*: "The problem of psychology in dealing with this complex subject matter is, in general—first, to ascertain its ultimate constituents, and secondly, to determine and explain the laws of its interaction." The elementaristic viewpoint of Ward must be modified, and three fundamental questions must be answered in a scientific analysis of a psychological problem:

- (a) What are the significant factors (variables, dimensions) that determine the behavior under investigation?
- (b) How do these factors determine the behavior? What is the stimulus-response relationship?
- (c) How do these factors interact?

The dimensional analysis may take place at an operational level, where the factors are controlled singly or in groups, i.e., the analysis may be unidimensional or multidimensional, or it may attempt to determine how the entire setting affects the result, i.e., it may investigate the interplay of the total forces within the field, in which case the emphasis is on the third objective referred to above.

Experimental psychology has no set procedures for the discovery of factors that determine behavior. Seldom can these factors be directly observed, and hence indirect modes of observation must often be utilized, provided that proof is forthcoming that they are valid indicators of the type of behavior being studied.

Then the ingenuity of the experimenter is put to the test, and in a preliminary investigation he makes use of all clues and all procedures that will disclose the factors at work, provided of course that the assumptions in regard to the relationship have been thoroughly tested. Thus he can observe the behavior under various stimulating conditions; if this variation is not carried out the study is only at a descriptive level, and many exploratory studies are of this nature. Sometimes a frontal attack, so to speak, is ineffective and in an attempt to surmount the difficulties residing in certain stimulus-response situations the experimenter must make use of alternative responses to the same situation, as, for example, when he uses the conditioned-response technique to determine the perception of sub-liminal stimuli. He may even in some types of preliminary work, e.g., the study of apparent movement, ask the subject for his introspections, so as to glean from them how the subject thinks that he experiences stimuli and how he varies his responses accordingly. All this, however, is but in the preliminary stage, and merely aids in the framing of hypotheses, which emerge from the predicated relationships of the variables, and which must then be submitted to rigorous tests and crucial experiments.

When these hypotheses are tested, and a series of measures of the various factors thought to be operative is obtained, the experimenter may conduct a factor analysis, the object of which may be, as Thurstone states, "to discover the principal dimensions or categories of mentality, and to indicate the directions along which they may be studied by experimental laboratory methods." T. V. Moore's factor analysis of the psychotic symptoms is an excellent case in point. This procedure is seldom carried out except in those fields in which the relationships are none too clear-cut.

With the object of exploring the factors which have been singled out for investigation, certain experimental conditions are compared with control conditions, to note if the differences then found in the means or the variabilities are statistically significant. Many psychological investigations stop at this point. Information thus

obtained, while valuable, is prone to be too disparate and unintegrated to be of real scientific worth.

When significant factors that determine a particular type of behavior have been discovered, a systematic dimensional analysis is then called for. One may determine (a) the absolute thresholds, i.e., the initial and terminal points on the stimulus range, that are effective in eliciting the behavior in question; (b) the relative thresholds (j.n.d.), or the increments of the stimulus that differentially affect the response throughout this range. It is to be noted that the study of the absolute and relative thresholds yield measurements, "not only of the appreciation of the minimal amount of differences in the stimuli, but also of measurements of narrow regions in the intensity scale in which sensory qualities change and in which new entities emerge" (Bartley). Much valuable information, e.g., by the critical flicker frequency in the field of vision, has been obtained by this oblique use of the threshold.

The next step is the traditional scientific procedure of factor variation. The functional relationship of stimulus and response is systematically explored throughout the range of the absolute thresholds, by keeping all factors except one constant, and by systematically varying that one, so as to note its effect on the response. At times a multi-dimensional approach may be made, and the methods of analysis of variance and of co-variance used to segregate the influence of the several factors.

The data from the dimensional analysis is generally expressed in the form of tables, graphs and equations. The equations may be descriptive only, based upon a curve fitted to the experimentally found points by the methods of moments or of least squares, or they may be based upon a rational formulation of the conditions obtaining, so that the constants in the equations have precise psychological meaning. When rational equations that are valid and thorough-going in application are obtained, the study has been completed in a truly scientific fashion, for not only have the dimensional

analyses been made, but their interactions are revealed by the equations, so that precise predictions under varying conditions may be made. Owing to the complexity of the factors influencing any particular situation and their dynamic character, it is not to be wondered that only in a few very restricted areas has psychology produced rational equations expressive of behavior.

Despairing of achieving such precise results without seriously distorting the situation, proponents of the field theories study the interaction of the various factors in a different fashion. Rarely do they attempt to control the variables; rather they let them operate freely, and then attempt to analyze their interaction. It is claimed that in life situations one thereby gains a more accurate picture of the total situation, although the dimensional analysis may not be carried out with the same precision yielded by other methods. In the more complicated situations of social, genetic, and abnormal psychology, the methods of the field theorists probably may yield more fertile results—and it is in these fields rather than in experimental psychology that they are more properly applied.

The foregoing statement sketches in broad lines only the steps to be followed in a thoroughgoing psychological analysis. It is understood of course that this sequence is seldom followed in its entirety. Little or no hints have been given as to the details of technique, or as to the devices used in practice to control the variables under investigation.

It is precisely in the manipulation of techniques that experimentation in psychology differs most radically from experimentation in other fields. The psychologist faces difficulties that are peculiarly his own. The paucity of clear-cut, objectively identifiable units of measurement is a problem that frequently confronts him, so that progress in any given segment of the field is slow until the type of behavior under investigation can be readily and accurately measured. Tied-in with this difficulty is the ambiguity of terminology, much of which is a heritage from time-honored phraseology. Most perplexing of all is the difficulty of isolating

for study many of the variables he wishes to study, for many of the powers of the normal human adult, e.g., attention, "form no psychic rubric of their own, but merely furnish the condition for the appearance of certain phenomena, so that some ascribe too little to them, and others too much" (Heening). Even when he flatters himself that he has isolated the requisite variables for study, the psychologist finds that it is almost impossible to maintain experimental conditions constant, due to the complexity and dynamic variability of the factors in behavior.

These and other obstacles demand specialized techniques, which differ for nearly every topic of investigation. They are so numerous that no description of them can be given here, and the reader is referred to the handbooks, such as those of Murchison, Woodworth, Dumas and Abderhalden, and especially to the original published material, for information as to the specific techniques in a given problem.

HISTORY OF EXPERIMENTAL PSYCHOLOGY

The history of experimental psychology is often placed as beginning with the publication in 1860 of Fechner's *Elemente der Psychophysik*; others prefer to assign as starting-point the establishment of Wundt's laboratory at Leipzig in 1879. The difficulty of assigning an exact date to the starting of experimental psychology as a separate subject matter within science is due to the fact that most of the material with which it deals has been studied empirically for centuries, and its scientific procedures had been developed mostly within physiology so that it was not easy to distinguish between the two.

Boring ascribes the influence of physiology and experimental psychology as originating from three main findings:

- (a) The Bell-Magendie Law (1811-1822), which proclaimed the structural and functional discreteness of the motor and sensory nerves.
- (b) Johannes Müller's (1826) doctrine of specific nerve energies.

- (c) Helmholtz's (1850) discovery of the velocity of the nerve impulse.

These important findings spurred on research in sensation, an interest which has been maintained in experimental psychology to our own day. He points out that discoveries important for psychology came also from other fields,—the contributions of physics on perceptual laws of vision and audition, the discovery of the personal equation by astronomers, 1820, which uncovered the very active field of reaction time, and the study of hypnotism which aroused interest in abnormal psychology.

It must be remembered that the original approach to psychology was through philosophy, which depended upon observation, introspection and empirical findings for its facts. Gradually through the centuries the need was felt for scientific procedures in the collection and collation of these facts. As Boring states: "Psychology grew out of the fusion of a philosophical psychology that had been going on within philosophy and a physiological psychology that had been developing within psychology." Only when scientists working in other fields investigated material of a psychological nature, by methods which were effective in their own disciplines, did the hope arise that psychology itself would become scientific, and that qualitative descriptions would give place to quantitative procedures. When, therefore, techniques were developed within physiology that gave promise of being applied to psychology, enthusiasm for the new science was aroused.

Investigation started early in several fields and has persisted to the present time, so that the content of experimental psychology has been clearly defined almost since its beginning on the basis of contributions from physiology and physics. Research in experimental psychology was chiefly confined at first to the fields of vision, audition, psychophysics, space perception and reaction time. Helmholtz published *Die Lehre von den Tonempfindungen* in 1863, before the completion of his monumental work, *Optik*, in 1867. The erudition, the precision of research, and the mastery of the interpretation which he brought to bear on these topics, gave

an initial impulse to the study of vision and audition which has enabled these ever since to maintain their dominance in the field of sensation. Other brilliant investigators like Hering, Aubert, and Brücke made important contributions at that early period chiefly to vision.

The publication by Fechner of his *Elemente der Psychophysik* in 1860 paved the way for fundamental investigations of mind by initiating methods which were purely psychological yet which could be applied to the field of sensation. His work stimulated men like Volkmann, Mach and Delboeuf in the field of psychophysics prior to Wundt.

Two other problems were then investigated in which interest has long since dwindled—the personal equation, studied by Donders in 1868, which started the vast literature on reaction time, and the study of the time sense under the inspiration of Mach in 1865 and of Vierordt in 1868. Some progress was made in the experimental investigation of taste, touch, rotation and space perception and the beginnings of an attack on the higher mental processes might be seen in Muller's work in 1873 on attention.

Such was the state of psychology prior to the publication by Wundt in 1874 of his *Physiologische Psychologie*, which gave a systematic exposition and an experimental orientation to the new science. Shortly after, in 1879, he gave a tremendous impetus to research by establishing the first laboratory at Leipzig.

Naturally the area which could be investigated by the new methods was narrow, and many topics, particularly those of thought, memory and will, at first seemed resistive to investigation, but they did not remain so long. It was Ebbinghaus who, inspired by Fechner's method in the domain of sensation, determined to investigate these processes, chiefly in the fields of association and memory. He devised his own material and procedures,—the nonsense syllables and the methods of complete mastery and of savings. In 1885 his epoch-making *Ueber das Gedächtnis* appeared, and opened up a new field which G. E. Müller and his associates developed, and in which has arisen a huge mass of research.

Research on feeling and emotion, one of the last fields of psychology to be studied experimentally, finally got under way under the inspiration of the James-Lange theory, 1884, and to some extent, of the discovery of the electric phenomena of the body.

With an initial body of data, in part borrowed from the cognate sciences, with a methodology of its own for the investigation of mental operations, and with research started in all its major fields, psychology stood on the verge of a tremendous expansion. Research laboratories sprang up, chiefly in Germany and America, and at least a score of them were operating prior to 1894. To record the work done therein, psychological journals began to appear. The principal ones with the date of their founding and their editors were:

Philosophische Studien, 1882, Wundt.

American Journal of Psychology, 1887, Hall.

Zeitschrift für Psychologie, 1890, Ebbinghaus and König.

Psychological Review, 1894, Baldwin and Cattell.

L'Année Psychologique, 1895, Binet and Beaunis.

Psychological Monographs, 1895, Angell.

Psychological Index, 1895, Warren and Farrand.

There have been many others, founded since, but these were the early journals of experimental psychology, and they still carry on. The *Philosophische Studien* was discontinued in 1903, and was replaced in 1905 by the *Psychologische Studien*, under the editorship of Wundt. It ceased publication in 1918. The *Psychological Index* was discontinued in 1936, but its work was taken over by the *Psychological Abstracts*, which were started in 1927, by Hunter and Willoughby.

The spread of experimental psychology into countries other than Germany, with the consequent diversification of viewpoint, is a matter of some interest. This is not the place to discuss the origin and tenets of the various schools, nor the polemics they occasioned, but since they did influence experimental psychology by steering research into definite fields and by focusing attention on specific problems, a brief survey of some of the more important systems seems called for.

The students who gathered around Wundt, worked in his laboratory and helped him expand the body of experimental findings and build up his psychological system, came not only from Germany, but also from France, England and America. When they returned to their own countries they brought with them an enthusiasm for research and a desire for the establishment of their own laboratories. Practically all the first-generation American psychologists studied under Wundt and, while many of them showed the influence of the master, their own work often developed along other lines.

Wundt's leadership was dominant over a period of some forty-five years, until his death in 1920. His systematic views were rigorously defined, and changed but little with the years; his psychology was essentially sensationistic, elementaristic and introspectionistic. Titchener, an Englishman who came to Cornell shortly after taking his doctorate in 1892 under Wundt, carried on for thirty-five years the Wundtian tradition in America.

The psychology of Wundt and Titchener was one of content, and narrowly followed the original lines of investigation of the fields of sensation and perception, to which were added in later years those of feeling, attention and association. In general the higher thought processes seemed as resistive as ever to the techniques of the classical investigators.

It must not be thought that content psychology held the field alone. Contemporaneously with the Wundtian school, the Austrian school, inspired by Brentano, and under the leadership of Meinong, Lipps, Benussi, Ach and Külpe, were developing what has been called art psychology. These men were essentially phenomenologists rather than experimentalists, and their theoretical orientation, their empirical approach, and their fields of investigation (thought, will, memory, imagination, space perception and aesthetics) differed considerably from those of the content school.

The reaction against the elementarism and the sensationism of Wundt was headed chiefly by the school of Gestalt psychology, which was an offshoot of the Austrian school. Its leaders were Wertheimer, Koffka and Köhler, its centre,

Berlin, and its chief organ, the *Psychologische Forschung*, founded in 1921. At the outset its main field of investigation was perception, chiefly that of apparent movement, but it rapidly turned to other fields. This was a powerful, aggressive new movement, with a well-integrated theoretical system which was essentially dynamic in viewpoint; more than any other it helped to correct the narrow static viewpoint of the older psychology.

In America, particularly, new systems opposed to Wundtian structuralism arose; for example, there was the functionalism of Ladd, James, Dewey and Angell. Most of these schools were short-lived, and were but variants of some pragmatic viewpoint, for the American psychology tended to be practical, applied, and to stress individual differences. It was also interested in animal psychology. From this interest which is reflected in the early work of Thorndike and Watson came the revolt of behaviorism against introspection and the mentalistic viewpoint generally. With the passing years the polemics of the early days have disappeared and behaviorism is no longer an issue, but fortunately the chief contribution of the behaviorists, the stressing of the objective and the scientific, has been taken over by the operationalists of the positivistic school.

Experimental psychology in France and England never did attain the same stature that it acquired in Germany and America, partly because it clung longer to a philosophic background, partly because its chief interests lay in other fields, applied, clinical or abnormal, and to some extent because the psychologists of these countries did not enjoy the academic prestige achieved by psychologists in America. There have been great British and French experimental psychologists, men like MacDougall and Pieron, whose writings and research have helped to make experimental psychology. That the output of research material in experimental psychology of France and England has been small compared with that of America and Germany, may be seen from the fact that the proportions that these countries have contributed to the total as recorded in the *Psychological Index* runs approximately as follows:—America, 35 per cent; Germany, 33 per cent; France, 15 per cent, and England, 3 per cent, with the balance contributed by other countries.

It is impossible to detail the progress that

has been made over the years and the changes which have occurred in experimental psychology. Information may be indirectly gleaned in other ways,—by the trend of the articles which have appeared, by the number of laboratories established, and by the research activities of members of certain scientific societies; studies have been made along all these lines.

Perhaps the most revealing of all those methods is the analysis of the publications which have been recorded in the *Psychological Index* since 1895, and in the *Psychological Abstracts* since 1927. These analyses of the material in the *Index* have been made by Maller and Goodenough over a forty-year period, and by Goodenough for the *Abstracts* over a six-year period. In the material that follows they are completed for the *Index* and are brought up to date for the *Abstracts*.

The literature is enormous. Some 157,086 titles were recorded in the *Index*; since it ceased publication in 1936, there have appeared 44,355 in the *Abstracts*. Of these 41,262 in the *Index* and 11,177 in the *Abstracts*, or 26.1 and 25.2 per cent respectively, are listed in the sections that are generally grouped under experimental psychology. More than 200,000 articles of which slightly more than one in every four is devoted to experimental psychology!

There has been a steady increase in the output, slowed down a bit by the world wars, from a yearly output of about 1,850 titles per year to a peak production of about 6,800 titles in 1931, retarded during the depression years, and advanced to 6,700 in 1938 and 1939, when the war brought another recession. Thus the amount of literature published in psychology has increased about three and one-half times since the appearance of the *Index*.

The proportions devoted to experimental psychology have tended to be fairly constant, with the following variations: Starting in the four-year period, 1894–8, with about 31 per cent, it increased rapidly to a maximum of 47 per cent in the four-year period 1902–1906. From 1910 on it has remained fairly constant, averaging around 27 per cent, in spite of the reductions in the war periods. The variations in the relative proportions of experimental psychology are to be found chiefly in the main fields of motor responses and of sensation and perception. The divisions of the higher mental processes—thought, attention, memory and learning and of feeling

and emotion have remained very constant except in the last decade, when their proportions have considerably increased. These proportions may be stated only in a general way, due to the changes in indexing, and the difficulties of noting with precision just what is the main topic of an article, as pointed out by Fernberger in his analysis of the material of the Abstracts from 1932-6. It is worthy of note that the first indexing of psychological publications was begun by Ebbinghaus and König in the first volume of the *Zeitschrift für Psychologie*, and was continued in substantially the same manner by the Index and the Abstracts. Minor variations in the mode of indexing have occurred from time to time, so that it is difficult to fix with precision the relative proportions of the literature devoted to any one field. The broad sections in the Psychological Index that come under the topic of experimental psychology, together with the percentage that each section is of the total amount of literature cited from 1894, is as follows:

- (a) Sensation and perception, psychophysics, 9.9%
- (b) Feeling and emotion, 1.4%
- (c) Motor phenomena and action, voluntary action, learning, work, fatigue, 10.6%
- (d) Attention, memory, imagination and thought, 4.7%

Substantially the same categories were used in the Abstracts as long as the Index was published. In 1937 they were modified, and the new sections, together with the percentages that these sections are of the total literature cited in the Abstracts since that period, are:

- (a) Receptors and perceptual processes, 10.2%
- (b) Learning, conditioning, intelligence, attention and thought, 8.7%
- (c) Motor and glandular responses, including emotion and sleep, 6.3%

Obviously the amount of experimental data, together with their theoretical framework, has reached the point where it is no longer possible to gather them in a textbook after the type of Wundt's *Grundzüge der physiologischen Psychologie*, the first edition of which appeared in 1874 and the sixth in 1908-1911, Külpe's *Grundriss der Psychologie*, 1894, or Titchener's *Experimental Psychology*, 1901-1905. Woodworth, after working diligently for some years,

published his *Experimental Psychology* in 1938. He admits the difficulty of keeping up with the literature, and acknowledged that he was obliged sharply to curtail some of its phases. As a consequence one may look for some kind of complete presentation only in the handbooks, which do not always cover all fields of psychology, or in monographs on specialized topics. There is a tendency now-a-days for both of these types of works to be the product of several writers.

Reviews on selected topics appear from time to time in the *Psychological Bulletin*. In their efforts to yield an exhaustive survey of the pertinent literature, they do not always give a balanced and integrated summary nor a critical evaluation of the material. A digest of the main findings and the generally accepted facts of experimental psychology on individual topics may be found in the *Encyclopedia*.

PRESENT-DAY ORIENTATION

The last decade has brought important developments in techniques, methods, and trends in psychology. The utilization of modern techniques and apparatus has permitted the precise investigation of phenomena, notably in the fields of vision and audition, as a result of which new chapters involving a wealth of carefully collated facts welded into workable theories have been added to our knowledge of sensation and perception. Data in nearly all fields are being subjected to a close scrutiny by modern statistical analysis, so that certain topics are becoming highly mathematical in treatment. Many of the statistical devices, such as factor analysis, are definitely the contribution of psychologists, and have been successfully applied in other branches of science.

Experimental techniques of some promise are being developed. Psychologists are no longer content with restricting themselves to psychophysical methods, which brought results where precision and elegance were obtained at the cost of artificiality of set-up and restricted applicability of results. Without forsaking these and other effective techniques, based upon rigid control of a single variable, new ones are being rapidly developed, where the emphasis is upon naturalness of the situation, economy of experimental design, and upon dynamic rather than static factors. As a result of attacks upon the

constancy hypothesis, multi-dimensional analysis, particularly in the field of learning, is steadily gaining ground.

Systematic programs are being carried out at certain centres, where research is concentrated upon well-defined problems, integrated to deal with definite and comprehensive areas, and developed along a theoretical framework. Such, for example, is the work done at Yale under Hall. The logic and fruitfulness of such a systematic attack as compared with sporadic and isolated investigations, no matter how brilliant, cannot be questioned.

The research inspired by theorists is no longer confined in the narrow fashion that formerly characterized the various schools of psychology. Modern psychology tends to become more and more eclectic, and proponents of all systems strive to incorporate within their theories proven experimental facts no matter what their origin. Broadened in scope, chastened by criticism, yet more tolerant of divergent viewpoints, experimental psychology is now well beyond the adolescent stage to which Titchener referred.

Not content to sharpen its attack upon traditional fields, psychology is submitting to experimental investigation branches and topics that for long years had been built up chiefly on an anecdotal, empirical clinical or theoretical base. Comparative psychology, of course, is the most outstanding example of this statement, but genetic, child, clinical and abnormal psychologies are now amassing a significant framework of experimental information. Possibly the healthiest sign of all is the collating of experimental fact from all branches of psychology to enlighten hitherto-isolated phases of psychology—such, for instance, as the bringing to bear upon the study of personality findings from widely separated fields of psychology, as evidenced by McVeigh Hunt's handbook, although it must be confessed the thread that binds them not infrequently seems tenuous and flimsy.

In an ever-widening circle experimental psychology is extending its field to cognate sciences, utilizing and amplifying the facts and theories of these branches to strengthen its own foundations. As a result, specialization is rapidly going on, not only within the major fields of psychology, but also on the fringes of physics, biochemistry, physiology, and other sciences. The trend is a healthy one, tending alike to keep psychology away from academic isolationism

and to emphasize the dynamic characteristics of all sciences that touch on man.

FUTURE DEVELOPMENTS

One might venture a prediction relative to trends in experimental psychology. Advances are to be looked for in apparatus design. Startling results are to be expected in fields where electronic equipment may be utilized, and already in electro-encephalographic and action potential studies, in nerve and muscle conduction, in vision and audition, notable advances have been made because electronic equipment has been adapted to those fields. One may expect that the work will go ahead rapidly and will be extended to other sensory fields, such as taste and touch, etc., which hitherto have been resistant to ordinary techniques. Continuous automatic recording of both stimuli and responses has long since been utilized and may be expected to be widely applied. Cinematographic studies have been used in many fields, e.g., comparative and child psychology, but ultra-high-speed photographic techniques will undoubtedly be developed for more precise studies in motivation, emotion, motor abilities, and possibly in personality and in other fields.

Experimental design will be refined,—precision and reliability of results will be achieved with greater economy of experimentation. Statistical treatment will acquire clearer psychological meaning without losing mathematical precision. The trend towards operationism will bring about clear-cut dimensional analysis of many at least of the variables that affect experimental results.

Standardization of units, procedures and terminology, a goal long since reached by the older sciences, and hopefully looked forward to by psychologists, probably will be achieved at least on a modest scale.

The precise role played by the nervous system will be disclosed, and generally speaking the compact integration of structure and function, of physiology and psychology, will be more effectively studied when electronic techniques are more widely applied. Possibly the electron microscope may yield facts of great portent relative to the structure and function of the cell and nerve fibrils. For so long has psychology talked uncertainly of the role played by the

synapse, etc., that positive facts would indeed be welcome.

Perhaps the development of the mathematical biophysics of Rashevsky, Householder, Landahl and others may tend to provide the requisite integration of neurology and psychology. Already these workers have made notable contributions to both fields, and many of their theoretical equations apply satisfactorily to experimental data.

Another contribution may be expected in the not too distant future,—viz., the repetition of some of the classic experiments, under more searching conditions and in the light of more recent findings and theories. Full confidence will not be established in published findings until these experiments have been duplicated in other laboratories and with varied samplings of subjects. As a result of the enormous expansion of experimental psychology in the armed forces, investigations will be undertaken on a scale that will make samplings of one hundred or one thousand subjects look small indeed. Fractionation of the data from repeated samplings of the subjects in these investigations will yield information relative to the predictive value of our statistical manipulations. Not the least of the contributions of this type of rigorous and exhaustive research will be the elimination of many hasty generalizations, based upon inadequate reliability. Psychology could make no more progressive move than the discarding of unfounded and unscientific statements from its texts.

Toward the goal of control and prediction of behavior, so elusive and so seldom approached in the past, vast strides will be taken when the dynamic factors as well as the static ones are taken into account. One may look forward to a development of the dynamic studies inspired by Lewin, Brown, and others to a clear emergence of principles determining the interplay of personality and social factors in behavior. Cross-sectional and longitudinal studies, closely but artificially controlled laboratory studies, to which methods psychology is deeply indebted for past contributions, will not be neglected, but the impact of field theories will be felt in the broadening of experimental objectives and the elasticity of hypotheses and interpretations.

Sooner or later experimental psychology must come to grips with problems of real life, enmeshed in their total setting, and not content

itself with the study of artificially restricted and, to that extent, distorted behavior. American psychology, with Cattell first to show the way, emphasized individual differences, even while prone to assume a constancy and a one-to-one stimulus-response relationship within the same individual that belied the real facts. Continental psychologists, on the other hand, have been more conscious of the kaleidoscopic changes of an individual's behavior in what superficially appears a constant stimulus-response relationship. These dynamic points of view are held mainly by what Dashiell calls the clinical psychologists, but many experimentalists are revising their own theoretical structures along some such lines.

As long as it was dominated by philosophy, experimental psychology advanced only too slowly. It still remains too physiological-minded to achieve maximum progress. Helpful as physiology has been in the past, all-important as are its contributions of the present, it has engendered too rigid and too simplified a mode of thinking to achieve optimum results. One need point only to the paucity of significant relationships found, say, in the study of feelings and emotions by physiological methods.

Most glaring of all is the inadequacy of such methods in the broad and important fields like imagination, thought, motivation and voluntary action. They are not unassailable to experimental psychology, but they will remain resistant so long as old-fashioned techniques based upon static theories are used. When some new Ebbinghaus appears to bring simple, effective, and perhaps daring procedures to bear on these problems, the elusive higher mental processes of early days, the real key to normal human adult behavior, may perhaps be found.

So complex is the living organism, so disparate and variable the external stimuli to which it is subjected, and so potent and labile are its internal forces that behavior cannot be expressed in simple terms, nor is it experienced in constant ways. Hence it is not to be expected that formulae of universal application will be found to characterize behavior. As experimental psychology probes deeper into the mystery of man, greater mysteries may be uncovered. Wider, surer knowledge there certainly will be, but hardly complete nor final.

EXPERIMENTAL ABNORMAL PSYCHOLOGY.

The segment of psychology that logically falls under the heading of Experimental Abnormal Psychology can be considered from a number of different points of view. If a rather broad point of view of the area to be discussed is accepted, the scope would include practically all phases of abnormal psychology. This would entail the writing of quite a number of volumes to cover the field adequately. The segment which will be discussed, therefore, is quite restricted in range. After careful consideration of the various aspects of the problem it has been decided that this exposition should be limited to the experimental attempts that have been made to bring about abnormal behavior by modifying some aspect of the internal or external condition of the normal organism. The reports of case histories of human beings; therapy applied to the already mentally disordered; discussions of psychological and physical traumas; and physiological and neurological changes manifested in the neuroses and psychoses do not seem to the author to satisfy the requirements of experimental abnormal psychology. In almost all of the preceding types of work information concerning the status of the individual before the abnormal behavior developed is lacking.

While numerous inferences may be drawn concerning causal factors at work and changes that have taken place, it is impossible to state in too many instances whether the variable factors that are encountered are concomitant with the disorder or are causal. For example, it is very difficult to ascertain whether a personality disorder following skull fracture is the result of the fracture itself or whether the trauma has only intensified already existing tendencies. Similarly, exposure to danger in battle with resultant neurosis does not clearly answer the question whether the battle situation was the precipitating cause or whether there were other

coexisting basic causes which heretofore had not been manifest. Clinicians are well aware that in most of their patients numerous and varied causes interplay with each other in producing the end result. The extent to which each of these causes contributes to the total can only be estimated, since they cannot be isolated, or factored out, or held constant. Much of the literature referred to in the source books which are usually thought of as falling in the field of abnormal psychology does not conform to our original definition in many respects. The experiments are not designed to bring about abnormal behavior in humans but rather to prove some theory of personality dynamics. With the exception of very few isolated studies on human beings and the vast volume of work on the lower animals, investigators have not produced behavior that would be designated as abnormal behavior by any currently accepted definition.

The various criteria of abnormality that have been set forth from time to time run the gamut from the simple self-comparison criterion to the mass-comparison criterion using the quantitative statistical approach. Both of these criteria are inadequate and both of them ultimately rely on arbitrary bases as to where the line of demarcation should be drawn. Other criteria which depend upon such concepts as social and individual harmfulness and lack of appropriateness are likewise not precise enough to give us a ready answer. Criteria for admission to mental hospitals are equally uncertain. A résumé of symptoms found in patients admitted to mental hospitals shows that our criteria are almost hopelessly confused. The symptoms include: behavior directly affecting the safety and welfare of others; behavior detrimental to the self; bizarre behavior; emotional and thought disturbances; speech abnormalities; memory defects; delusions; hallucinations; and psychomotor disorders. Not all of the symptoms are encountered in every case and there is considerable overlapping of symptoms in the various cases.

This report is not concerned primarily with the controversy of criteria of abnormal behavior as to whether a person is sane or insane in a legal sense. The issue cannot be avoided ultimately if any assay is to be made of the field of experimental abnormal psychology. Similarly, it is impossible to avoid the problem of separat-

ing the field of abnormal psychology from the fields of neurology, physiology and medicine. Although mind and brain depend upon each other, they certainly are not the same. Mind depends upon physiological and neurological conditions, yet a complete understanding of neurology and physiology cannot insure an understanding of mental capacity and human activation. With respect to that which is mental, the organism is in a constant state of flux. Every stimulus is subjectively different from all previous stimuli due to prior experience and the results of modification of mental life by prior experience. Therefore the need of developing a more thoroughgoing "psychology" cannot be overemphasized.

A suggestion recently made to the writer seems to offer a reasonable basis for determining whether behavior is normal or abnormal. If the individual voluntarily relinquishes responsibility for his behavior or if society compels him or her to relinquish control of his or her behavior, then the behavior may be considered abnormal.

It should be pointed out again that it is doubtful whether phenomena that could be defined as abnormal by such definitions have been produced experimentally. Experiments on human beings, on aggression, repression, submission and frustration show that behavior can be modified in accordance with the theories promulgated and within the limits of the framework of the experiment. It is highly dubious whether either a true neurosis or true psychosis has ever been produced by such experiments. Almost all of the investigators imply that if the experiment demonstrates the theory held, then similar activities carried far enough or extended to other fields of activities would produce "abnormal behavior."

The inclusion of experimental work on infra-human species presents still other problems. Is the behavior which is obtained "abnormal"? Can it be inferred that the behavior is psychologically produced? Can causal relationships based on analogous reasoning be classed as sound bases for explaining abnormal behavior in human beings?

Let us examine some of the investigations that have been carried out by experimenters in both the human and infra-human fields. Let us determine whether they satisfy the general rules of a well planned experiment. Further, let us

ascertain whether they are experiments dealing with the production of abnormal behavior.

If we examine a typical case history, a clearer picture of the use of case histories as they may be applied to experimental abnormal psychology may be obtained. The following case of involuntional melancholia illustrates the general symptomatology and furnishes the basis for a practical discussion of cause and effect.

Diagnosis. Involuntional melancholia. F. F., female, aged 50, married, Jewish.

Main Facts. The patient is a tense, meticulous person who has been treated for fifteen years for indigestion. At the menopause she became worried and censured herself about the acquirement of property which was later disposed of at a sacrifice. She was restless, depressed, discontented and went from hospital to resort without improvement. She finally refused food, denied the existence of her family and thought she was a "stone."

Family history. While a number of the members of the family are neurotic no frank mental illness is admitted.

Personal history. The patient was born in Germany, and came to the United States at the age of 16. She had pleurisy, neuritis, and an ovariectomy and appendectomy. She had been treated for indigestion for 15 years. Puberty was established at fifteen and was irregular with dysmenorrhea. There was an artificial menopause with flushes following an ovarian operation. The patient was married to a traveling salesman at the age of seventeen and has two sons. She was active, tense, enjoyed cards and loved her home. She was rather moody with swings of elation and withdrawal from friends, rather than depression.

Two years ago she bought an apartment house and was somewhat elated over her purchase, but when her husband did not approve she became worried. She was emotional, anxious, and began to have a feeling that it must be disposed of. This was finally done at a considerable loss. Several months later she complained of depression, anxiety, and felt that she must leave home. At a health resort there was some improvement but a mild accident accentuated her gastrointestinal symptoms. She could not sleep, was dreamy, had no interest, and changed hotels in one city several times. Then she complained of being heavy, dazed, and fearful of impending disaster. She became listless and in-

different, denied the existence of things and refused to accept her sisters as her family.

In the first month of her hospitalization she answered all questions with "yes" and "no," "I don't know—don't remember," and was preoccupied, depressed and tearful. Occasionally she would say, "I am too heavy. I can't read or move. I can't do anything. I am a stone." At other times she asked the nurse, "Are you me? I am not me. I don't know why—I am nothing. I weigh only ten pounds. I am little and dirty—it is just like a baby crying." In answer to questions she said, she was "supposed" to have had a husband and "supposed" to have had a family. She thought that everyone was against her and that she was the only one left and believed that all those about her were ghosts. She said she had no stomach, called the hospital a prison, misinterpreted the ward activities and denied the existence of everything. She continually talked about her unworthiness and remarked that everything was lost and she would never recover. Her movements indicated retardation and difficulty in execution of activity, while her facial expression was one of distress, apprehensiveness and depression. She said she had been a liar and deserved to be punished, that she has had unpleasant thoughts about her family and has treated them badly. Later the feelings of unreality became accentuated and she refused to eat, saying she had no stomach and had turned to stone.

The patient gradually became more childish in behavior and was frequently seen weeping, "me can't—me can't do it—me too little—me too dirty." She crawled about on the floor, refused her food and cried, "Oh my—me so little—you so big." She became increasingly untidy in her habits and resistive to any care, refused to go to the toilet saying "me don't have to go to the toilet—me don't have to have bowels moved." She had to be bathed, dressed and tube fed and became more and more resistive and abusive. She talked like a baby, muttered to herself and dribbled saliva like an infant.

The patient slowly but gradually improved and began to speak of learning to walk and talk and slowly developed an interest in adult things. Her interests and abilities in occupational and recreation classes were carefully watched and fostered and she began to show a more adult attitude. She was allowed to visit home periodically and slowly began to take

over her duties at home. At the present time she has been out of the hospital for two years and is doing well.

It can be discerned readily that both psychological and physiological causes are at work. Whether the symptoms presented would have developed in the absence of either of these factors is impossible to state. We cannot be sure, therefore, what the causal factor really is. If we refer to one theory for explaining the mental content of such patients a line of reasoning similar to that which follows would be employed. There is an increasing egoism which is equivalent to restriction of external interest. Since pure egoism finds no satisfaction in this life, there follows preoccupation with death. Along with the desire for death, there is, frequently, however, revulsion against it, since egoism implies resistance to death. The presence, in the same patient, of apprehensions of death together with suicidal attempts clearly shows these two tendencies. Insomnia in these patients may then be accounted for on the basis of the fact that sleep is the symbol of death. Nihilistic delusions appear when the loss of interest in the world is projected. Since things are no longer desired, their existence is denied. Other authorities point to the gradual decline in health and vigor, the increase in chronic illness in family and friends, as well as in one's self, coupled with the realization that time is passing swiftly, and that the attainment of ambitions is not likely to occur. This second line of reasoning differs very much from the first one. Still a third line of reasoning is possible. Since there is evidence of glandular dysfunction due to the menopause, the mental symptomatology may be explained on this basis. It can be demonstrated further that hormones of various kinds alleviate many of the mental symptoms in some cases of this type. Which of these lines of reasoning is correct? There is no answer to this question. The answer depends in part upon the theory held by the therapist.

Case histories are deficient in a number of respects and cannot be included under the heading of experimental abnormal psychology. In spite of the fact that they supply much needed information for therapeutic purposes they do not enable one to show distinct cause and effect; nor do they usually throw much light on the period prior to the episode, since much of this information has to be gleaned from other people

whose memory of pertinent facts is extremely poor.

A case reported by Kraines illustrates the causal factors at work in mental disorder following brain injury:

"Mr. S. M. was a window washer in a large firm. He fell three stories one day and fractured his skull, wrist, and nose, and was unconscious for about an hour. He remained several weeks in the hospital; but when he recovered from his physical bruises and injuries he found that he could not concentrate; forgot easily; was dizzy most of the time, had frontal and right-sided headaches, slept poorly, saw double at times and at other times 'couldn't see for a moment or two'; always felt tired; was unable to read even the daily newspaper; and worst of all, flew easily into rages at the slightest irritation, and on occasion had struck his wife. He was home for six months, and then was given a position as a janitor. He had a cash settlement for his injury and was content therewith. Since that time, however, the symptoms enumerated above had continued despite the fact that all physical examinations were negative. He was diagnosed as a neurotic because there was no physical indication of his disabilities, and because of his emotional outbursts."

"Study of his background revealed the ordinary difficulties and the usual mother-in-law problems, but these same problems had existed before the accident, and he not only was unaffected by them but was a happy and hard-working person. Psychotherapy was useful only in that it made the patient less intolerant of his inability to work, but it essentially did not change his symptoms. The so-called neurotic symptoms were in all probability based on actual damage to his brain tissue, the damage probably being multiple petechial hemorrhages in the silent areas. In this case there was definite evidence of skull fracture, but in many instances there may not be any skull fracture, and the damage to the brain and personality may be as great or greater."

In this case there are certain indisputable facts. The patient fell and received physical injuries. He developed mental symptoms which persisted after recovery of the physical injuries. There are, in addition, certain unknown or uncertain facts in this situation. What was the extent of the brain injury, if any? Are the cir-

cumstances surrounding the accident entirely responsible for the mental symptoms? Since psychotherapy did not entirely succeed, is it logical to assume that there must be brain injury? We might inquire whether some other form of psychotherapy would succeed. Further, it is pointed out by Kraines that study of the patient's background revealed ordinary difficulties that might produce such symptoms. While many of these questions might be answered on theoretical bases, the end result is that we still cannot say with certainty what the real cause is.

Pathological changes in brain structure are often assigned as causes of mental disorders. For example, changes that occur as a result of syphilis and brain tumor may be accompanied by well systematized delusions and hallucinations. There is no question about the existence of abnormal behavior, but how the brain structure change produces the mental disorder is another matter. Delusions of grandeur, accompanied by syphilis, may disappear after diathermy treatment. No one assumes that the spirochetes themselves cause the peculiar mental symptoms. Nevertheless after the spirochetes are killed off the symptoms may be abated. Explanatory recourse is made to vicarious functioning of other parts of the brain; to resumption of function of certain brain areas due to reduction of inflammation in non-destroyed areas. These two attempts at explanation are directed toward a functional viewpoint which might be termed psychological. Other theorists attempt to explain the delusional systems on personality trends co-existing at the time of destruction. In other words, these theorists try to explain why one person develops delusions of grandeur and another person develops delusions of persecution. It is certainly true that a study of tissue pathology will not suffice for these explanations. We are still groping in the dark for a satisfactory psychology that can be applied to these problems.

Let us consider next a case of nervous anorexia, since it will serve to illustrate certain problems related to physiological changes and mental disorder.

A male college student about 25 years of age reported for his first job after finishing college. Three days later he vomited shortly after coming to work. This continued for several days. The vomiting gradually extended so that he

could retain no food. Medical advice was sought but no physical basis for the difficulty could be discovered. The patient became prostrate and had to be hospitalized. He continued to lose weight, became seriously depressed and almost died. Psychotherapy was instituted. It was soon discovered that the patient had a deep conflict about his impending marriage. When this problem was ironed out recovery took place at a rapid rate.

This case seems to present clear-cut psychological problems from which it seems possible to construct adequate psychological cause-effect relationships. Reiss, on the contrary, reports that some cases of almost similar kind did not respond to psychotherapy unless adjunct therapy with hormones, particularly those of the pituitary gland, was instituted. The difficulties of distinguishing between the organic and ideational bases of the disorder are still extant. Since such disorders may be brought about by either organic or psychological causes, or by both, our conclusions can be only relative and tentative and do not satisfy the requirements for a clear-cut experimental abnormal psychology.

In drug addiction, where the effects are chiefly physiological in the initial stages, it is assumed that the habit is based largely on physiological need. This point of view can be argued more forcefully from the fact that addiction has been produced experimentally in primates. These animals presumably do not have the psychological problems that would lead to addiction. This point of view is often held with regard to humans, namely that conflict and the desire to escape from their problems lead to drug addiction. It may be questioned seriously whether human beings deliberately decide to become addicts. It is also doubtful whether a human being to whom the drug is administered with full knowledge of its consequence and with the understanding that an addict was to be made of him or her would go through with the experiment. Even if the experiment were carried out, there remains the question whether the individual would continue to be an addict. It is quite possible that the ideational factors would be such that the habit would be immediately thrown off in spite of the apparent physiological need. The uncontrolled factors in drug addiction are so numerous that it is unsafe to state positively cause-and-effect relationships. Saul's analogical explanation of a case of

sion is determined in part by the object of fixation, the strength of the drive and the strength of the frustrating agent. One of the theories to account for schizophrenia is that of regression. The individual, unable to cope with life experiences, adopts (regresses) an earlier form of behavior in which the responsibilities of life no longer have to be met. In this situation we might expect intellectual regression as well as behavior regression. Although Cameron's studies of the already mentally disordered cases do not conform to our original definition, he has examined the reasoning of schizophrenics and he does not confirm the fact that intellectual deterioration takes place. A study by Du Bois and Forbes on the regressive tendencies of catatonics to assume foetal positions during sleep does not show that these positions are adopted more frequently by abnormal cases than by supposedly normal cases. Both of these experiments illustrate the high variability of responses in both normal and abnormal people. If some do and some do not, how are individual differences to be accounted for? Can we show that normal subjects subjected to repeated frustration revert uniformly to these forms of behavior? The work of Mowrer, Hamilton, Krechevsky, Maier, Miller and Sears on animals tends to show that under appropriate conditions some form of regression takes place. Is this due to the limited repertoire of response? Is this due to a restriction of ideational processes in the lower animals? Masserman draws upon the experimental work on animals to explain rituals, obsessive behavior, negation, masochism and sexual aberrations, yet when he discusses the experimental work on psycho-surgery he inclines toward reduction in variability of response and stereotypy in behavior as accounting for such behavior. He would seem to imply by analogy that intellectual and ideational processes are the most important factors in producing behavior anomalies. Such processes as these are most generally accepted as being restricted in the lower animals.

One of the modes of response to the normal sex drive when that drive comes in conflict with the environment is substitution of non-conflicting modes of satisfaction. This is referred to as substitution or sublimation. A classic example of sublimation centers in the sadistic tendency of man. This is the tendency to inflict punishment or practice cruelty on the object which is

loved. A surgeon may be manifesting the normal response to this thwarted tendency. That is, he cuts and hurts people, but in the reversal of the process he heals them rather than hurts them. A man whose impulses would indicate a long list of murders and other crimes, by sublimation turns out to be a writer of crime and detective stories. Actors and actresses may be supposed to have had a strong tendency toward exhibitionism or narcissism. Their sex urges are sublimated.

If individuals who have made a successful social adjustment (i.e., do not have neurotic symptoms) in nearly all respects to the sex drive, are studied carefully, we might not expect them to resort to autoerotic experiences or illicit heterosexual experiences. One study, nevertheless, indicates that these so-called normal healthy and otherwise well adjusted individuals respond to their sex drives by resorting to types of behavior that may well be labeled as deviating from normal behavior. On the whole, the theory of substitution or sublimation is a beautiful theory but the mechanisms involved are shrouded in mystery and do not satisfy the criteria for experimental abnormal psychology.

An impulse that results in frustration accompanied by painful experience may be repressed, i.e., the behavior accompanying the impulse may disappear. Similarly, ideational representation of the impulse may be inhibited. Some writers have translated the Freudian concepts into reflex terminology. Extinction of a response becomes the equivalent of repression; inhibition with the negative phase and reinforcement with cathexis. The theory has been approached from a number of different points of view. One approach is that of studying recall of pleasant and unpleasant experiences. If repression is a dynamism that really functions, then more pleasant than unpleasant experiences will be recalled. The results of this line of experimentation are not unequivocal. The bulk of the evidence, however, seems to support the thesis.

Another approach is that of using an experimental situation in which failure is the punishing agent of the ego. When children or adults are unsuccessful do they tend to repress (forget; the response becomes extinct)? An experiment by Rosenzweig will illustrate the method. Two groups of students were presented puzzles to solve. One group was told that the puzzles were a type of mental test, hence their performances

indicated their mental ability. The second group was told that the experimenters were interested only in ascertaining information about the puzzles, so that the individuals' performance was not personalized. Later both groups were asked to recall the completed and uncompleted tasks. The first group recalled more of the completed tasks whereas the second recalled more of the uncompleted tasks. Since the first group had a conflict over their failure and the second group did not, repression supposedly took place. While this type of experimentation throws light on the theory stated earlier, it does not demonstrate that abnormal behavior necessarily arises in this manner. All learning situations usually involve failure, otherwise the individual would have no knowledge of when responses are correct or incorrect. As Dunlap has pointed out, in the course of learning the individual is constantly "unlearning" and relearning. Further, he has shown that the "final response" which we call "correct" is not identical with any previous response. While these experiments are ingenious, it is only by unwarranted extension of interpretation that we can apply them to abnormal phenomena.

In the field of animal experimentation we are beset by all of the problems stated earlier in this report; the main problems being whether the behavior exhibited by animals is abnormal and whether theories determined from behavior exhibited in the narrow framework of the laboratory situation can be applied to human beings. It has been shown that various sub-human species—rats, dogs, sheep, pigs and primates—can be treated in such a manner that they will exhibit behavior which appears similar to abnormal behavior in human beings. Symptoms similar to those that occur in people are undoubtedly encountered in animals. Anxiety (manifested by bodily disturbances such as muscle tension, heart rate changes, respiration changes, etc.) apparent fear or phobia, repetitive and stereotyped behavior (compulsive behavior), adopting simple or prior modes of response (repression), and sex perversions have been brought about. Whether this behavior is explained by conditioning theories, psychoanalytic theories, field theories, or some other theory makes little difference. The two questions that have to be answered are (1) Is the behavior abnormal? and (2) Does human abnormal behavior develop in the same way? These criteria

have been proposed for evaluating animal behavior: (1) Is the behavior maladaptive? (2) The maladaptive behavior must be exhibited in a situation that has been met in a more adaptive manner; (3) The maladaptive behavior must be present as long as the animal is subjected to the precipitating situation. Can these criteria be applied successfully to abnormal behavior in human beings? It is relatively simple for a person to say that animal behavior is maladaptive, but is the behavior really maladaptive for the animal? We do not know enough about ideational processes in animals to make this inference. When this criterion is applied to the human species the problem is much more complex. Is tobacco smoking maladaptive? It depends on one's point of view. Is masturbation or homosexuality maladaptive? This depends again on the point of view taken. In some cultures such behavior may be considered maladaptive, in others not. If an animal continues to select the longer of two pathways to food, even though the animal previously selected a shorter pathway, can this be said to satisfy the second criterion? This situation may be compared with that of the human being who continues to work for a lower salary even though he previously earned a higher salary and the opportunity still exists to earn the higher salary. No one would seriously contend that the individual in question is abnormal. We would argue that all the circumstances for explaining the behavior are not clearly enough known. The third criterion is inextricably tied up with the first two. If a rat is forced to discriminate between two stimuli that are near his threshold in order to obtain food and exhibits a disorganized type of response or manifests bodily disturbances, we interpret such behavior as maladjustive behavior. It seems to the writer that the behavior, on the contrary, is highly adaptive for the situation. It is true, nevertheless, that a human being who has heart palpitation, excessive perspiration, or stomach disturbances resulting from an emotional situation that cannot be solved would be classified as a neurotic. Both the rat and the human may show different behavior upon removal of the stress situation. Both may show a continuation of the behavior. In some cases, however, we cannot predict what will happen. Here we run into the problem of individual differences that cannot be explained by the experiment or by the information available con-

cerning the human being. This last factor is a very important one and needs further study.

Our problem becomes progressively complex if we examine further some facts relative to the production of abnormal behavior in lower animals. The conventional methods of producing neurotic or convulsive behavior in rats is to subject them to air blasts, loud noises, jingling noises, difficult discrimination situations and electric shock stimulation. We assume that maladaptive behavior occurs as the result of being unable to escape from these situations. It has been shown that rats if allowed to seek cover in a closed compartment do not show as marked a tendency to be disturbed. It is obvious that the environmental situation is important. Even in the absence of escape possibilities rats do not uniformly exhibit the behavior. Genetic factors seem to be important. Strains of rats produced by inbreeding are more susceptible. Similarly wild rats and tame rats behave differently. Can these differences be explained by the simple experimental situation? Dietary factors can also be shown to contribute to the end result. Deprivation of Vitamin B complex tends to increase the maladaptive behavior. What is the relation of these various factors? No one can answer this question accurately. Neurotic behavior in adult persons has been brought about by a deficiency of the Vitamin B complex and psychosis occurs as a result of nicotinic acid deficiency. Yet not all human beings with the same degree of deficiency will develop neurosis.

Experimentation on hoarding of food, selection of diet, modification of behavior by destroying brain tissue furnishes valuable insight into the controlling factors of normal and abnormal behavior. Criticism of the kinds already mentioned may, however, be leveled at these types of experimentation.

On the whole, the field of experimental abnormal psychology has been approached indirectly. This may be the only possible approach, since experimenters are unwilling to run the risk of creating abnormal behavior in human beings and are unable to control all of the variable factors that enter into the production of such behavior.

EYE, THE.—The human eye (bulbus oculi) is the organ of sight centered each in the cavity of its bony orbit within the frontal plane of the skull where it is suspended within enveloping sheets of adnexae and rotated by the attachment of six muscles. Associated with it are certain accessory structures bearing an intimate functional relationship including the eyelids, the conjunctivae, the lacrimal apparatus, the extraocular muscles, the fasciae, fatty tissue, blood-vessels and nerves.

Each orbital cavity is roughly the shape of a quadrilateral pyramid whose base is parallel to the frontal plane of the skull and whose apex is directed backwards towards the occiput. The bony mosaic of each cavity contains the lacrimal bone and the os planum of the larger ethmoid bone, and planes of the frontal and sphenoid bones. Towards the apex the orbital cavity presents three foramina or openings which permit the transmission of important structures between the eye and the cranial cavity. These include (1) the optic foramen transmitting the optic nerve and artery, (2) the superior orbital fissure transmitting the ophthalmic vein, the third, fourth and sixth cranial nerves and the first branch of the fifth cranial nerve and (3) the inferior orbital fissure which transmits the infraorbital artery and maxillary nerve. The invagination of the human eye within the cavity of the bony orbit in contradistinction to the location of the organ of sight in some of the more primitive vertebrates is a development which serves to protect the human organ from traumatic injury.

The somewhat flexible suspension and fixation of the eye within the orbit is effected by three enveloping structures namely (1) the orbital fascia or fibrous tissue sheet, (2) the conjunctiva and (3) the lids. The orbital fascia serves as periosteum firmly bound to the bony walls of the orbit from where it is reflected to cover the globe from the corneal margin to the optic nerve (Capsule of Tenon), to form a

septal prolongation joining the tarsal ligaments and to invest the extraocular muscles, thus binding them to each other, to the lids and to the margins of the orbit. The capsule is pierced by all of the structures which enter the globe and within the fascial folds are found branches of the ophthalmic artery and vein (communicates to cavernous sinus), the three cranial nerves supplying the extraocular muscles, sensory branches of the fifth nerve and the ciliary ganglion. This ganglion lies just to the outer side of the optic nerve and receives motor fibres from the third cranial nerve, sensory fibers from the fifth cranial nerve and sympathetic fibers from the carotid plexus in the neck. Its short ciliary nerves enter the posterior pole of the globe. Long ciliary nerves from the sympathetic supply smooth muscle fibres sparsely distributed in the capsule and their tonicity serves to check the inward pull on the globe by the action of the extraocular muscles. Hypertonicity of these muscles due to sympathetic stimulation causes protusion of the eyeballs as observed, for example, in exophthalmic goiter. During ocular rotations both the globe and investing capsule move together as a unit upon a cushion of surrounding adipose tissue (fat).

The conjunctiva is a thin, transparent layer of mucous membrane covering the front of the globe excepting the cornea and investing the inner surfaces of the lids. It extends from the circular cornea at the latter's margin (limbus) and covers the anterior globe as far as the base of the lids where it is reflected at the fornix to cover the inner lid surfaces. The conjunctiva is sensitive, being abundantly supplied by branches of the fifth nerve. It contains lymphatics and is provided a vascular supply from two systems, i.e., the posterior conjunctival from the palpebral, which is the more superficial, and a deeper anterior ciliary. The conjunctival membrane provides not only a sensitive protecting surface to the front of the globe but serves as an anterior supporting membrane and a smooth surface for the gliding of the lids over the eyeball.

The eyelids (palpebrae) consist of a larger upper and smaller lower fold of skin (integument) lined by conjunctiva and containing areolar tissue, fibrous tissue, muscle, blood-vessels, nerves and glands. The fibrous tissue in the form of comparatively dense horizontal

bands (tarsi) is attached to the lateral orbital borders by the external and internal tarsal ligaments and to the orbit above and below by the tarso-orbital fascia. The tarsal plates thus formed furnish a semi-flexible support to the lids. The lids are closed by the contraction of the circular orbicularis muscle supplied by the seventh cranial nerve and opened by the contraction of the vertically acting levator palpebrae superioris muscle which is supplied by the third cranial nerve. The tarsi contain some strands of smooth muscle supplied by sympathetic nerve fibres (Mueller's muscles) whose stimulation effects involuntary twitching of the lids. The tarsal plates contain a row of sebaceous glands (Meibomian glands) which are filled with a fatty secretion and open along the free margins of the lids where the secretion serves to lubricate the tissues and prevent the overflow of tears when the latter are secreted at the normal rate.

The outer and inner lid margins are referred to as the outer and inner canthi respectively, and located at the inner canthus a small reddish elevation of modified skin, the caruncle, is observed. The eyelashes (cilia) border the free margins of the lids and are supplied with sebaceous follicles (Glands of Zeiss) and modified sweat glands (Glands of Moll). The arterial pattern of the lids is in the form of two anastomosing vascular arches derived from the ophthalmic and facial arteries. The veins empty into the ophthalmic, temporal and facial veins and the lymphatics drain into the preauricular, submaxillary and parotid lymph glands. The sensory nerve supply is derived from the fifth cranial nerve. The lids and cilia protect the eyes from injury, foreign bodies and excessive light at the same time serving to distribute the tears and glandular secretions over the conjunctiva, thus maintaining the exposed portion of the globe lubricated, moist and transparent.

The excretory part of the lacrimal apparatus consists of the lacrimal glands, small oblong bodies composed of acini of cuboidal cells similar in structure to the salivary glands, situated in the upper and outer portions of each orbit. The excretory ducts from the gland pass downward and empty by separate orifices along the external half of the conjunctival fold at the fornix. Thus the tears are excreted from the upper outer surface of the conjunctiva and wash downwards and inwards to be collected at the

two inner canthi by the puncta which open into the lacrimal sac through two small canals (canaliculi). The lacrimal sac is a small reservoir composed of fibrous and elastic tissue and lined by mucous membrane which contains a row of ciliated columnar epithelial cells. The sac lies in a groove formed by the lacrimal bone and the frontal process of the maxillary bone. The tears are swept from the sac to the inferior meatus of the nose through the lacrimal duct which leads downwards, outwards and slightly backwards from the sac. The lacrimal excretion is slightly alkaline, saline and bacteriostatic. It serves to wash foreign material from the conjunctival sac, to keep the eye moist and to provide an antiseptic lotion against the inroads of pathogenic bacteria. When the eye is irritated and under emotional stress and lacrimal excretion is greatly increased.

THE OCULAR GLOBE AND TUNICS

The outline of the globe may be considered as being formed by the segments of two spheres, the smaller and outer (whose circumference corresponds to the ellipse of the cornea) being above twelve millimeters in diameter, and the larger and inner (whose circumference corresponds to the ellipse of the sclera) being about twice the diameter of the smaller. The cardinal points which are concerned with the disposition of incident and emergent light rays within the eye may be conveniently enumerated as follows:

(1) *Principal Points*. 2.0 mm. behind the cornea in the anterior chamber being points so situated that when incident rays pass through one of the points the corresponding emergent ray passes through the second point.

(2) *Nodal Points*. 7.0 mm. behind the cornea near the posterior pole of the lens representing the optical center of the eye, incident rays passing through being axial or secondary rays and not refracted by the dioptric system.

(3) *First Principal Focus*. 14 mm. in front of the cornea where parallel rays in the vitreous meet.

(4) *Second Principal Focus*. 23 mm behind the cornea between the macula and the disc where parallel rays meet after being refracted by the dioptric system of the eye.

(5) *The Center of Rotation*. 10.0 mm. in front of the retina in the vitreous.

(6) *The Optical Axis*. A line connecting the

center of the cornea, the nodal point and the posterior principal focus.

(7) *The Visual Line*. A line passing from the object of regard through the nodal point to the macula.

(8) *The Line of Fixation*. A line joining the object of regard with the center of rotation.

(9) *The Angle Gamma*. The angle formed by the optical axis with the line of fixation.

(10) *The Angle Alpha*. The angle formed by the visual line with the major axis of the corneal ellipse.

The tunics of the globe consist of three portions, i.e., (1) an outer supportive layer made up of the fibrous sclera and transparent cornea, (2) a mesial nutritive layer comprised chiefly of vascular tissue divided into the iris, ciliary body and the choroid (uvea) and (3) an inner perceptive layer, the sensitive retina, composed by the expansion of the optic nerve (end organ of sight).

The Sclera. The sclera or outer coat of the globe is about one millimeter in thickness and is composed of tough, opaque and inelastic fibrous tissue of about the same consistency of peritoneum. It furnishes the necessary strength to contain the intraocular pressure and the required rigidity to enable the function of the extraocular muscles which are firmly attached to this layer. The sclera is invested by Tenon's capsule and is pierced posteriorly by the optic nerve at the lamina cribrosa.

The Cornea. The cornea is the circular transparent portion of the front of the globe being a continuation of the sclera but with a somewhat shorter radius of curvature than the latter from which it is demarked by a circular region referred to as the limbus. The cornea is made up of five layers, i.e., an outer layer of epithelium, Bowman's membrane, a connective tissue stroma comprising most of the corneal thickness, Descemet's membrane and an inner layer of endothelium. Capillary loops from the anterior ciliary vessels encircle the cornea and provide for its nutrition through a network of lymphatic lacunae and canals distributed throughout its stroma. The cornea is very sensitive, being supplied by numerous twigs from the fifth cranial nerve. The cornea forms the front window of the eye, transmitting and steeply refracting entering light waves. Local irregularities of the anterior surface of the cornea (irregular astigmatism) and symmetri-

cal disparities between the radii of curvature of opposite corneal meridians (regular astigmatism) both serve to distort incoming light rays.

The Iris. The iris is the colored circular curtain forming the anterior part of the vascular and nutritive uveal tract and is suspended behind the cornea and in front of the lens, thus dividing the anterior chamber into an anterior and posterior part. The connective tissue stroma of the iris is spongy and contains branched pigmented cells, circular (sphincter pupillae—3rd nerve) and meridional (dilator pupillae—sympathetic nerves from the cilio-spinal center of the lower cervical spinal cord) muscle fibers, two anastomotic vascular rings derived from the posterior ciliary, the anterior ciliary and the ophthalmic arteries and which communicate at the crypts of the iris with the anterior chamber, thus permitting rapid exchange of aqueous from the iris to the anterior chamber and vice versa. The iris is covered anteriorly by endothelium and posteriorly by a limiting membrane and retinal pigment layers. Iris tissue is very sensitive, being supplied by numerous branches of the fifth cranial nerve. The center of the iris is perforated by an expansile circular aperture, the pupil, whose diameter is varied by the interaction of the circular and meridional muscle fibres for much the same purpose as we vary the diameter of the lens aperture of a camera. In this manner the amount of light which enters the eye is regulated and the marginal rays which would interfere with the clarity of the image (spherical aberration) are cut off. Normally the pupil contracts upon exposure to light, with accommodation and convergence, a phenomenon effected by the circular fibers of the sphincter pupillae muscle, the efferent impulse coming from the third nerve nucleus in the floor of the Aqueduct of Sylvius, to the third nerve trunk, to the ciliary ganglion and finally by the short ciliary nerves to the sphincter muscle. The light reflex may be direct or consensual, the latter phenomenon being explained by the fact that the light stimulus in one eye is carried by the optic nerve and passes to both optic tracts and in this way to the nucleus of the third nerve of each side. Dilation of the pupil may be due to paralysis of the third nerve (paralytic mydriasis) or to excessive stimulation of the sympathetic (spastic mydriasis). Contraction of the pupil may be due to stimulation of the third nerve

(spastic miosis) or to paralysis of the sympathetic (paralytic miosis).

The Ciliary Body. The ciliary body is the wedge-shaped part of the tunica vasculosa and extends from the posterior base of the iris to the anterior part of the choroid. The ciliary process is very vascular, being supplied by the greater circle of the iris plexus and the anterior ciliary arteries, and nutrient material is secreted therefrom to the cornea, the lens and part of the vitreous. The ciliary veins pass to the vortex veins of the choroid, while some of the veins from the ciliary muscle pass backwards, pierce the sclera and run beneath the conjunctiva with the anterior ciliary arteries. The ciliary body contains unstriated muscle tissue supplied by the third cranial nerve which, upon contracting, draws the ciliary process and choroid forward and inward, thus relaxing the suspensory ligament of the lens and releasing the tension of the lens capsule, thereby permitting the lens to assume a more convex shape (accommodation). Tschering has advanced the theory that the contraction of the ciliary muscle increases the tension of the suspensory ligament and that this causes a peripheral flattening and an anterior bulging at the center. The purpose of accommodation is to furnish a dynamic residuum of focusing adjustment of emerging light rays so that a clear image is focused on the retina. We have seen that the greatest refraction takes place at the cornea but this is a fixed quantity and static. The auxiliary focusing power of the lens through the action of the ciliary muscle permits a finer adjustment which may be varied to the need.

The Choroid. The choroid forms the posterior part of the uveal tract and extends back from the ciliary body to the posterior pole ending at the optic disc where its pigment is observable in the form of a dark circular ring. The choroid is arranged in five layers and is composed of a rich network of anastomosing vessels and pigmented cells. The function of the choroid is to furnish nutrient material to the retina, vitreous and lens. We have noted that the uveal tract contains an abundance of pigmented epithelium. The amount varies with the individual, being greater in persons of dark complexion and less in blond individuals. In albinos this pigment is lacking. The purpose of the pigment may be considered as an adaptation to absorb and dampen excessive light.

The Retina. The retina is the transparent expansion of the optic nerve lining the interior of the globe and extending from the entrance of the nerve at the disc (3.0 mm. to the nasal side of the posterior pole) forward to the ora serrata of the ciliary body. It is traversed by the retinal vessels which enter the globe with the nerve. The arteries are non-anastomotic or end arteries. From within outward the retina is composed of the following layers, i.e., (1) the internal limiting membrane, (2) the nerve fiber layer containing the vessels, (3) the layer of ganglion cells, (4) the plexiform layer, (5) the inner nuclear layer of bipolar cells, (6) the outer plexiform layer, (7) the outer nuclear layer, (8) the external limiting membrane, (9) the layer of rods and cones and (10) the layer of pigment cells. A little to the temporal side of the posterior pole and below the horizontal plane of the globe is a small ovoid glistening area of retina 1.5 mm. in diameter, the macula lutea, in the center of which is a small depression, the fovea centralis. This is the region of central direct vision where the visual acuity is the highest and we receive a clear and detailed impression of an object upon which we fix. Visual acuity diminishes rapidly beyond the foveal area. In this sensitive area we find long narrow cones but no rods. From the macula towards the periphery of the retina the rods increase in number until they predominate over the cones in the more peripheral area.

Scotopic or twilight vision is sensitive to low light intensities and to motion. It is achromatic, insensitive to red, with the greatest luminosity perceived in the region of the green band of the spectrum. It is presumed to be the more primitive visual faculty and is effected by the retinal rods which increase in number concentrically towards the periphery. The low light threshold in scotopic vision is conceivably due to the following factors:

(1) The anatomical arrangements of many rods being connected to a single ganglionic cell (via bipolar cells), thus summing subliminal stimuli and decreasing the threshold stimulus.

(2) The relative abundance in the rods of a bleaching substance in the form of a conjugate protein rhodopsin (visual purple) which absorbs some light rays converting photic energy to a nerve impulse in the analysis of a complex chemical compound to simpler ones which apparently irritate the rods to form an impulse.

The photochemical change or phase of vision may be summarized as follows:

When light strikes rhodopsin the luminosity of the spectral region around 530 M μ (green) is absorbed and changes the rhodopsin to retinene (visual yellow), a compound resembling carotene which is the precursor of Vitamin A, and then to a colorless substance identical to Vitamin A. It is supposed that the simpler chemical compounds resulting in the analysis of rhodopsin irritate the rods sufficiently to generate a nerve impulse. Under the influence of light the retinal pigment migrates between the rods and cones as far as the external limiting membrane. In the dark the retinal pigment withdraws towards the nutrient choroid and collects around the external segments of the rods where rhodopsin is synthesized by the action of Vitamin A, retinene and a colloid in a period of time ranging from ten to forty minutes. In the process some of the Vitamin A is lost and must be replaced through the circulation from its storehouse in the liver. Nyctalopia or "night blindness" occurs in some degree when the above outlined processes are interfered with in any way.

Photopic or daylight vision (light-adapted eye) is a function of the retinal cones in the perception of detail (form sense) and in the perception of colors (central vision). The photopic threshold is higher than the scotopic due to a decreased amount of photochemical pigment (visual violet) as compared to the rods and to a decrease of stimuli summation in the cone connectors as the macula is approached. (Light threshold 0.0134 with maximum in yellow-green at 580 M μ and chromatic at 0.25 meter-candles.) It is postulated that the original and primary function of the cones is light perception mediated through a photochemical process and that color perception is a later specialized function of the cones. It has been presumed that in cone function the primary and elemental gray perception has evolved to yellow and blue perception and that yellow perception further evolved into the perception of red and green by an anabolic process (Ladd Franklin) which is reversed by katabolism of the same process. It is true that colors of extremely high intensities produce a sensation of gray (katabolism) and that the fusion of complementary colors produces gray.

Hue is the cone reaction to a specific wave

length. Saturation is the absence of foreign wave lengths in a hue and refers to the spectral purity of the color. Luminosity (yellow) is an intensity value either depending on rod-cone balance in dim light or to a katabolic hue change in the direction of the elemental gray and away from specificity. In the study of color vision certain terms are used which will be enumerated as follows:

Trichromatopia. All hues may be obtained by the physical admixture of bluish-red, green and violet. (Toned by yellow, black and white.)

Dyschromatopia. Defective color perception. It is hereditary, occurs more frequently in males and is transmitted by the female. An acquired form is occasionally seen in certain ocular and systemic diseases.

Achromatopia. Total color defect usually accompanied by albinism and nystagmus. May be due to the congenital absence of the secondary chromatic factor of the cones.

Dichromatopia. All color sensations produced by the admixture of two colors.

Protanopia. Red defect with neutral band at blue-green (492).

Deutanopia. Green defect with neutral band at red (502).

Tritanopia. Blue defect with neutral band at yellow-green (570).

In the study of retinal function it is to be remembered that the image of an object viewed appears in reverse form on the retina so that objects to the right activate the nasal half of the right retina and vice versa. Similarly an object above is perceived by the lower half and an object below is perceived by the upper half of the retina. The extent of the peripheral or indirect fields of vision as measured on the perimenter with central fixation using a 10 mm. white test object at a distance of one-third meter is as follows:

	Out	(Degrees)		Down
		Up	In	
Form (white)...	90	55	60	70
Blue	80	50	50	60
Red	70	40	40	50
Green	60	30	30	40

Visual Acuity or the direct central form sense is the smallest visual angle at which the form of objects can be distinguished and is repre-

sented by the least distance between two objects at which they can be distinguished as two. The smallest visual angle or resolving power of the human eye is conveniently assumed to be an angle of one minute or a retinal image of about 0.004 mm. in diameter, and since the diameter of a retinal cone is approximately 0.003 mm. it is believed that there is a physiological relationship between the two and that two points can be seen separate only when they are large enough to cover more than one cone. The cone mosaic of the retina at the fovea is so arranged that two lines are seen as separate more readily than two points, and the minimum separable of two such lines is ten seconds of an arc and is known as the aligning power of the eye. The size of the retinal image varies directly with the size of the visual angle, which is determined by the distance of the object of regard from the nodal point of the eye. The visual acuity is measured by the ability of the eye to distinguish letters or figures, preferably of Gothic style, under an illumination of at least twenty foot-candles of white light; such letters being black on a white or gray background and of a size which subtends an angle of five minutes, each component block and separation thereof subtending an angle of one minute for the specific distance at which the letter or figure is placed from the nodal point of the eye. For testing purposes an adequate distance is twenty feet or six meters.

The Optic Nerve. The optic nerves terminate a short distance behind the globe at the chiasm which lies in the optic groove on the sphenoid bone which is in front of the infundibulum and above the hypophysis. In the chiasm the fibers of the optic nerve separate to form a semi-decussation with the following pattern, i.e., fibers from the nasal half of each retina (temporal visual fields) cross over to continue in the optic tract with fibers from the temporal half of each retina (nasal visual fields) which do not cross but continue back, in their original retinal relationship. It is thus apparent that from the optic chiasm back the right retinal halves (left halves of visual fields) are represented in the right half of the brain while the left retinal halves (right halves of visual fields) are represented in the left side of the brain. From the chiasm the optic tracts are conducted back around the crura cerebri to the primary optic ganglia (the external genicu-

late body, the anterior corpus quadrigeminus and the pulvinar of the optic thalamus) where the fibers divide. The smaller portion of this division passes to the nuclei of the third cranial nerve (oculomotor nerve), thus establishing the pupillary reflex and movements of the ocular muscles. The larger bundle of fibers are concerned with visual impressions and pass through the posterior portion of the internal capsule and then fan out to form the optic radiation (fibers of Gratiolet) which terminate in the cortical ganglion cells of the mesial surface of the cuneus and the parts surrounding the calcarine fissure of the cerebral cortex (visual area). In this area nerve excitations become visual sensations and visual memories.

THE CONTENTS OF THE GLOBE

The Vitreous. The vitreous is a transparent gel filling the larger chamber of the globe situated behind the lens. It is slightly condensed towards the periphery and contains the hyaloid canal which runs in an antero-posterior direction and which encloses the hyaloid artery during fetal life. The canal serves as a posterior fluid passage and the vitreous gel forms a slightly compressible bulk which fills out the larger chamber of the globe helping to maintain its internal pressure.

The Aqueous. The iris divides the aqueous into an anterior and posterior chamber. The iris angle is formed by the junction of sclerocorneal margin, the root of the iris and the ligamentum pectinatum whose elastic laminae are covered by an extension of posterior corneal endothelium, thus forming spaces which are continuous with the cavity of the aqueous (spaces of Fontana). At the sclerocorneal junction Schlemm's canal communicates laterally with the anterior ciliary veins. The aqueous humor is a nutrient fluid secreted by the ciliary process into the posterior chamber and carried by convection through the pupil to the anterior chamber leaving the eye through the spaces of Fontana and Schlemm's canal into the anterior ciliary veins. The posterior fluid passages include the hyaloid canal and to the vortex veins via the suprachoroidal space and Tenon's space. The intraocular pressure is the result of the ratio of aqueous secretion (dialysis?) and drainage and remains fairly constant at a normal figure of 25 mm. Hg.

The Lens. The crystalline lens is suspended

in its transparent capsule behind the iris by two ligaments attached to the ciliary body. It is formed by accretion of successive concentric lamellae to a biconvex transparent body 5 mm. thick and 9 mm. in diameter. The function of the lens is to focus divergent rays of light on the retina which is effected by a total increase of convexity brought about by the contraction of the ciliary muscle which draws the choroid forward and relaxes the suspensory ligament of the lens, thus diminishing the tension of the lens capsule and allowing the lens to form a more convex shape (Helmholtz), or the ciliary contraction increases the tension of the ligaments, bulging the lens forward anteriorly at the center (Tscherning). Regardless of the mechanism an increase of convexity is obtained which is dependent upon the elasticity of the lens fibers and is termed accommodation. When this elasticity is decreased, as it is in old age to a very appreciable extent, divergent rays are not readily brought to a focus and objects at near distances are not seen clearly (presbyopia). In the study of accommodation the following terms are used and the appended table illustrates the loss of accommodation with advancing years.

Far Point. The farthest point of distinct vision with the accommodation relaxed. In the normal eye this is at infinity.

Near Point. The nearest point at which the eye can see distinctly when employing its maximum accommodation.

Range of Accommodation. The distance between the far point and the near point.

Diopeters of Accommodation. The convex lens value which it would be necessary to place before the eye to take the place of the accommodation for the near point. The focal length of a one diopter lens is 100 centimeters or one meter.

Amplitude of Accommodation. The difference in diopeters between the refractive power of the eye at rest and when accommodation is exerted at its maximum.

AC equals 100 divided by NP in cm.

Relative Accommodation. The dioptric amount that accommodation may be relaxed (negative) or augmented (positive) while fixation at a certain convergence distance is maintained. This illustrates the existence of a certain elasticity between accommodation and con-

vergence and is equally true of the latter function.

TABLE OF ACCOMMODATION AMPLITUDES
AND NEAR POINTS

Age yrs.	Amplitude D	Near Point cm.
10	14.00	7.0
20	10.00	10.0
30	7.00	14.0
40	4.50	22.0
50	2.50	40.0
60	1.00	100.0
70	0.25	400.0 (Duane)

OPTICAL CONSIDERATIONS AND MOTILITY OF THE EYE

While all ether vibrations travel at the same rate they differ from each other in wave length so that while the rate of propagation remains constant the number of vibrations per unit of time differs. The range of known ether vibrations from the shortest wave length of 0.004 millimicrons (one millimicron equals one one-millionth of one millimeter), which is known as the cosmic wave of Millikan, to the longest radio or Hertzian waves, measuring seven kilometers to 100,000 millimicrons, traverses seventy octaves, of which only one octave (760 to 380 millimicrons) is perceptible to the human organ of sight.

It was previously mentioned that the cornea refracts divergent light rays entering the eye so steeply that rays originating from a point six meters distant can be considered parallel in the sense that they are exactly focused on the retina after traversing the refractive media (cornea and lens) without additional focusing effort on the part of the lens, providing the eye is normal (emmetropic). It can be stated, then, that in the emmetropic eye light rays from a point recedes to forty centimeters or beyond, upon the retina when the eye is at rest and the accommodation relaxed. Divergent rays originating from a point closer than six meters will require additional focusing and this is effected by an increased convexity of the lens mediated through the ciliary muscle in the act of accommodation as described before. When fibrosis of the lens progresses to the point where its focusing ability decreases so that the near point recedes to forty centimeters or beyond,

presbyopia has arrived and the individual will experience difficulty with near vision. The focusing power of the lens is readily understood when we consider the optical fact that when light rays enter a prism (a triangle of glass base down) they are bent or deflected towards the base. Now if two prisms are placed so that their bases are in apposition it is apparent that entering light rays are bent towards each other (focused) until they meet at a point (principal focus). This is the shape of a convex lens and the shape of the crystalline lens of the eye which alters its principal focus by altering the amount of convexity, which is the same as increasing the width of the base of a prism.

If the indices of curvature of the refracting media are less than normal, or if the antero-posterior diameter of the globe is less than normal, parallel rays entering the eye at rest will focus behind the retina and hypermetropia results. The eye tries to compensate by accommodating and may do so, in which case vision is maintained with effort which may cause fatigue (asthenopia), or if the goal is beyond the accommodative power the latter relinquishes its effort with the result that accommodative strain is avoided but the visual acuity for distance is decreased. If the indices of curvature of the refracting media of the eye are greater than normal or if the antero-posterior diameter of the globe is greater than normal or if the indices of refraction of the refracting media are increased (sclerosis), and if the lens fibers become swollen (cataract), parallel rays will be focused in front of the retina, and since accommodation cannot compensate by diverging light rays, distant visual acuity is proportionally decreased and the condition of myopia results. The individual compensates somewhat by holding objects closer to the eye, thus diverging incoming rays by approximating his fixation to suit his needs. In employing the term "normal" in the above discussion it must be remembered that, strictly speaking, an absolute normal does not exist, so the referred "normal" must be taken to mean the focusing norm of the individual eye which focuses rays from a distance of six meters and beyond exactly on the retina without accommodative effort.

When the indices of curvature of any of the refracting surfaces of the eye are greater in one meridian than the other it is apparent that the

opposite meridians will be focused on planes of a different level, so that one meridian may be focused on the retina but its opposite will not, so that distortion will result and the condition of astigmatism is present. So far as is known the lens is unable to accommodate sectionally, so the condition is not compensated for and visual acuity is decreased. The asthenopia which very frequently accompanies even small amounts of astigmatism may be explained upon the basis of an abortive attempt to compensate by accommodative effort or upon the basis of fusion difficulty, or both. Irregular astigmatism is a distortion of the image produced by a localized irregularity of a refracting surface as, for example, that caused by the scar resulting from a corneal ulcer. Irregular astigmatism usually causes grave visual defects and, of course, is not compensated for by accommodation. Anisometropia is a term applied to mean a difference in kind or degree of refractive error of one eye as compared to its fellow. Since accommodation is the same in both lenses it is apparent that compensation will be attained, if attained at all, in but one of the eyes (usually the most emmetropic eye) and that asthenopic symptoms will not only be accommodative in nature but fusional as well, as the images formed will show some disparity.

Under normal conditions both eyes are concerned in the act of vision, and when an object is fixed the eyes involuntarily assume a position so that the object is focused on the macula of each eye and more peripheral rays are focused on corresponding retinal points. The blending of the two images into a single mental percep-

tion is termed fusion, a faculty acquired soon after birth and usually well developed by the end of the sixth year of age. The act of fixation or looking at an object may be voluntary or reflex, but the neuromuscular act providing for singular binocular vision is reflex just as accommodation and convergence are reflex. We have seen that objects are projected in reverse order on the retina so the upper field falls on the lower retina, the inner field on the outer retina and so on. By reversing this process we learn by experience to judge the location of an object by placing it at the extremity of an imaginary line drawn from the retinal image through the nodal point of the eye (projection).

Normally both eyes move simultaneously and so conjoined that the images of an object always fall on corresponding retinal areas. Ocular movements may be described as rotations around a vertical (abduction-adduction), a transverse (supraduction-infraduction) and an antero-posterior (torsion) axis whose center of rotation is about the center of the globe. These conjugate movements of the eyes are effected by the action of the six extraocular muscles attached to the globe and anchored at the orbital planes. The complex rotations involving a fine balance between action and brake action (check) is regulated and governed by neural centers of association. In every movement of the eyes several muscles of each eye act simultaneously but the field of action of an individual muscle is considered that direction of gaze in which its action is greatest. The following table summarizes the extraocular muscles, their nerve supply, their primary and their subsidiary actions:

<i>Muscle</i>	<i>Nerve</i>	<i>Primary Action</i>	<i>Subsidiary Action</i>
External rectus	6th	Abduction (out)	None
Internal rectus	3rd	Adduction (in)	None
Superior rectus	3rd	Supraduction (up)	Adduction-intorsion
Inferior rectus	3rd	Infraduction (down)	Adduction-extorsion
Superior oblique	4th	Infraduction (down)	Abduction-intorsion
Inferior oblique	3rd	Supraduction (up)	Abduction-extorsion

Somewhat different from the above outlined yoke movements of the eyes and effected by the simultaneous action of the internal recti muscles in association with accommodation we are able to rotate each eye inward when fixing objects at close range. This constitutes the act of convergence and is measured by the meter angle

one unit of which is the angle formed by the visual line with the median line at a distance of one meter. Thus when an individual fixes an object at a distance of one meter, each eye accommodates one diopter and converges one meter angle (normally). While the association of accommodation and convergence is intimate

in the fixation of near objects in order to enable us to see these objects both clearly and singly, it is not, however, inflexible, and accommodation can act separately, as we have seen, and so likewise can convergence, such action being termed relative convergence—positive when it increases and negative when it decreases beyond the fixed value for the distance involved.

Fusion, or the mental blending of two images as one, depends upon the integrity of the afferent arc of the visual reflex, the integrity of the co-ordinating centers and the efficient or normal operation of the efferent neuro-muscular arc. The first requires that two similar and clear images reach the brain and this, in turn, depends upon clarity of the refractive media, freedom from high and dissimilar refractive errors and normal neural conduction to and through the centers. The second requires an efferent neural pathway free from disease or abnormality and functionally efficient muscles so placed that the posture of the eyes is within the range or amplitude of fusion. When any of these conditions do not prevail the retinal images of an object do not fall upon corresponding retinal areas and double vision (diplopia) results. Eventually one of the images becomes mentally suppressed, and the eye in which the image is suppressed deviates from parallelism and moves with its fellow dysjunctively. This latter phenomenon is termed strabismus, squint or heterotropia. It is further differentiated into paralytic strabismus when the efferent neural pathway or individual muscle is affected by dis-

ease or injury, and concomitant strabismus when the afferent pathway or muscular posture is involved. Fusion, or the desire to see singly, is tenacious when once acquired and serves to further orient the eyes into exact binocular alignment over and above that supplied by the neuro-muscular postural tone, much in the same manner that accommodation supplies the extra focusing power over and above that supplied by the static cornea required to focus a sharp image on the retina so that we are able to satisfy our demand to see clearly. The exercise of each function in the overcoming of handicaps results in compensation with strain and fatigue, while failure to overcome the handicap results in a loss of clarity on the one hand and diplopia with the final dysjunction of an eye on the other. The fusion power may be roughly assessed by allowing the eyes to overcome an artificially produced diplopia by employing prisms (ductions) and by measuring stereopsis and comparing it with a standardized norm. This latter test rests upon the fact that true depth perception (perspective) is produced by the fact that the two eyes regard an object from slightly different angles (interpupillary distance of about 64 mm.) and the supposition that when the fusion faculty is well developed one's stereoscopic perception is proportionally high. It is true, of course, that stereopsis is lost when one eye suppresses even momentarily.

Lewisburg, Pennsylvania

F

FEEBLE-MINDEDNESS (MENTAL DEFICIENCY).—Mental deficiency is a condition or state characterized by mental and social inadequacy resulting from arrested or incomplete mental development. The term is used also to refer to the field of interest centering upon the study, training and care of those who are mentally defective. Conditions involving behavioral, mental and emotional disorders of other than developmental origin until recently have received little attention from psychologists and are generally considered as almost wholly within the province of the medical sciences. Mental deficiency, on the contrary, has been long regarded as within the province of psychologists who thus have been in a position to make, and have made, many contributions to its study. From the field of mental deficiency, in turn, have come contributions to our knowledge of general psychology. Mentally defective subjects have afforded unique opportunity for investigation of specific psychological problems, exploited chiefly in studies of intelligence and mental development. Foundations for present-day clinical psychology were laid by those who first undertook application of psychological methods to the study of the mentally deficient. Psychological work in mental deficiency has contributed importantly to the field of tests and measurements, and has in many instances had a significant influence upon instruction and organization within university departments of psychology. Results of research with mental defectives have also influenced thought and research in other fields, especially that of normal child development.

Knowledge of the more general features of mental deficiency is prerequisite for appreciation of the psychological material which this condition presents. Although an extensive literature is available, it is widely scattered. A considerable portion of this report, therefore, is devoted to a survey of general features (terminology and definition; history; systems of classification; incidence, causation and control; treatment, care, training and supervision). Not

only is this important as background, it also represents much material contributed by psychologists, sometimes incidentally to other work.

GENERAL FEATURES

Terminology and Definition. The condition of mental deficiency (Ger. Schwachsinn; It. deficiencia mentale; Fr. *débilité mentale*;) has also been called in English *idiocy*, *imbecility*, *feeble-mindedness*, *amentia*, *mental subnormality*, *hypophrenia* and *oligophrenia*. At one time considerable confusion arose because *feeble-mindedness* was used in the United States to include all degrees of mental defect, while in Great Britain the term referred only to the less pronounced conditions of those called "morons" in America. *Amentia* has been used more widely in England than in the United States, while *hypophrenia* and *oligophrenia* are not yet generally accepted terms, though the latter is now found increasingly in the medical literature of both countries. *Idiocy* and *imbecility*, on the other hand, are no longer used as generic terms, though both have been retained in English as in the European languages, the former to designate the extreme degree of defect, and the latter the next less severe degree. *Mental subnormality* occasionally used to designate the entire range of mental deficiency, generally refers to conditions found among those who are called high grade, or borderline, defectives, or to children who are "backward," or "retarded," but not truly defective. An arbitrary distinction is commonly made between the higher grade subnormals and the "true defectives," idiots, imbeciles, and low grade morons who require either permanent or temporary custodial care. It is recognized, however, that mental deficiency in the sense of limited intelligence is common to the individuals of both groups though in differing degrees.

Definitions of mental deficiency have been formulated in the fields of medicine, psychology, law, education and social welfare. Each formulation tends to emphasize particular aspects of the condition or the problems it presents to the field in question. A definition given

by Esquirol is said to have been the first clear definition of "idiocy" and has not been surpassed since his time.

"Idiocy is not a disease, but a condition in which the intellectual faculties are never manifested; or have never been developed sufficiently to enable the idiot to acquire such amount of knowledge as persons of his own age, and placed in similar circumstances with himself, are capable of receiving. Idiocy commences with life, or at that age which precedes the development of the intellectual and affective faculties, which are from the first what they are doomed to be during the whole period of their existence."

The following definition is given in the English Mental Deficiency Act of 1927:

"Mental defectiveness means a condition of arrested or incomplete development of mind existing before the age of eighteen years, whether arising from inherent causes or induced by disease or injury."

Widespread use in the United States of the Binet-Simon intelligence test method and acceptance of a theory of mental deficiency as a quantitative deviation, i.e., the condition characterizing the low end of the curve of distribution of intelligence, have contributed to definition of mental defect in terms of Mental Age and Intelligence Quotient. In 1910 the American Association for the Study of the Feeble-Minded defined the various levels of mental defect in terms of mental age, considering a mental age of 12 years at maturity the lower limit for the non-defective population. Later an I. Q. of 69 (mental age 11 years at maturity) was accepted as the upper limit for mental defectiveness and this is still specified in the laws of New York State and of some other states as a criterion for commitment to an institution for defectives. The figure, 70 I. Q., is frequently cited as a point of demarcation between the defective and non-defective populations even though clinical findings have demonstrated that at the borderline level an intelligence quotient, alone, is insufficient for establishing the condition of mental deficiency. Moreover the percentage of the population which would be considered defective by this criterion is far in excess of any reasonable estimate of true amentia.

A broader formulation, but offering no specific criteria, appears in the *Statistical Manual for Use of Institutions for Mental Defectives*.

"The condition of mental deficiency, or the diagnostic mental status, is to be determined by a combined consideration of all clinical data relating to the patient, that is, his present mental condition as to intelligence level and emotional reactions in relation to his anatomical, physiological and neurological constitution; his general behavior and social adjustment; his background in biological and social heredity; and his genetic developmental history, including particularly events affecting his physical, social and emotional development. In short, all those data which are necessary in order to evaluate the present status of the individual."

There are two conditions with which mental deficiency may easily be confused. The first is simple subnormality. The distinction between socially inadequate individuals of low intelligence and those of the same intelligence level who are capable of "managing themselves and their affairs," and do not require "care, supervision or control for their own protection or for the protection of others" is primarily social and calls attention to the over-all nature of the condition of mental deficiency. This appears clearly in the social criterion of defect accepted in Great Britain. At younger ages, before social competence is established, test results have offered an alternative criterion, and these are now being increasingly used.

Secondly, mental deficiency should be differentiated from those deviations from the normal found in mental disease or psychosis. Deficiency is frequently confused with certain psychotic states because of behavioral similarities as well as somewhat superficial correspondence in the legal, medical, and social aspects of the problems presented by the two groups. Indication of retarded mental development (determined by study of the developmental history) is the distinguishing feature of the mentally defective, and usually constitutes the basis for differential diagnosis. Though distinct medical and psychological conditions, mental defect and mental disease are not mutually exclusive and there is good evidence that a close relationship does exist between them. Nearly every form of mental illness has been found among defectives and the incidence of psychoses in individuals of sub-average intelligence is so high as to have led to the suggestion of special susceptibility to mental disease among those who are intellectually sub-normal.

HISTORY

The earliest records of attention to the mentally defective include: the Therapeutic Papyrus of Thebes in 1552 B.C., (considered the first account dealing with the care of mentally subnormal children); a report by Juan Pablo Bonnet, a physician of Madrid who, in 1620, undertook the education and physical rehabilitation of a mentally defective deaf-mute; and the teachings of Boerhaave at the University of Leyden, Morgagni of Padua, and Haller of Göttingen all of whom in the 18th century instructed their students in mental deficiency. Scientific interest in mental deficiency is considered to date from the work of the young French physician, Itard, whose efforts to educate "the savage" or "wild boy" captured when eleven or twelve years of age in the woods of Aveyron and diagnosed by Pinel as an "idiot," were officially reported in 1801 and 1806 and excited wide interest.

Itard's detailed reports of his painstaking, ingenious, exploratory studies of the defective boy, Victor, have become a classic in the literature of clinical psychology, education and mental deficiency. There has been little recognition, however, that many of the procedures employed by Itard (such as, for example, serial exploration, recognition, and paired association) anticipated methods later identified with the early psychological laboratories. Itard's pupil, Séguin, elaborating upon his predecessor's system of "medical education," published in 1846 his "*Traitément Moral Hygiène et Éducation des Idiots et des autres Enfants Arriérés*," known as one of the first psychological contributions to the study of the idiot and imbecile. Séguin's "physiological method," based on the theory that "the education of the senses must precede the education of the mind," consisted in the main of carefully prescribed courses of sense and habit training. His teachings set the pattern for a group later referred to by Binet as "clinicians who have made . . . a vague pedagogy adorned with the pompous title of the medico-pedagogical method."

The zeal of Séguin (better known to the psychologists today for the Séguin Form Board than for his writings) found a second avenue for expression in the founding of schools for the training of defectives. After establishing the first successful institution of its kind in Paris

in 1837, he emigrated in 1850 to America, where he became associated with Samuel Howe (teacher of Laura Bridgeman) and other pioneers of the American movement to provide for the mentally deficient. The first schools for defectives in Germany, Switzerland, and England had been established in 1842. In the United States, Massachusetts opened the first state-supported school in 1848, and by 1876, when the "Association of Medical Officers of American Institutions for Idiots and Feeble-minded Persons" held its initial meeting with Edouard Séguin as president, there were twelve such institutions in the United States.

Two circumstances favored the development of institutions. The first was the discovery that no amount of training would make the idiot self-supporting. The second resulted from early studies by Goddard and Davenport emphasizing the importance of heredity in transmission of the higher grades of mental defect, and the relationship of this condition to pauperism and crime. Communities were encouraged to protect both society and the individual defective. By 1917 institutional care was provided by all but four states. Between 1890 and 1942 the number of feeble-minded and epileptic persons in public institutions in the United States increased from 4,001 to more than 105,000. This increase, though attributable in part to the general increase in population, is due chiefly to an increase in institution facilities.

The introduction of the Binet-Simon scale into America by Goddard, Huey, and Kuhlmann began a new era. Fernald, long a leader in the study of mental deficiency, considered that "the theory and practice of mental testing and the discovery of the concept of mental age did more to explain feeble-mindedness, to simplify its diagnosis and to furnish accurate data for training and education than all the previous study and research from the time of Séguin." Among the diverse and far-reaching effects of the use of the intelligence tests between 1910 and 1925 was the immense widening of the field of academic psychology to include clinical and applied psychology.

A research department, organized for psychological studies in mental deficiency, service to the institution, and the training of psychologists for clinical work, was established at the Training School at Vineland, New Jersey, in 1906. This department, under the leadership

successively of Goddard, Porteus, and Doll has made steady contribution to the fields of mental deficiency and psychology. It has also set a pattern for the organization of similar departments (but with programs varying in emphasis) in other institutions, including Letchworth Village of the New York State Department of Mental Hygiene, the Wayne County Training School in Michigan, the State School at Wrentham, Massachusetts, and the recently opened Training School at Southbury, Connecticut.

The mental testing program of World War I and the widespread introduction of group tests into school systems brought to public attention the problem of the higher grade subnormal groups. As a result, the field of mental deficiency has come to be roughly subdivided into two areas of interest. The first centers about problems of those of lower mentality, the "true defectives," of whom a considerable percentage are to be found in institutions. The second is concerned with the high-grade and borderline groups remaining largely within the general population. Of the latter group, only a small fraction are institutionalized, and those often for short periods only. The two areas differ widely as to medical, legal, biological, educational, social and psychological importance, although there is no clear dividing-line between them.

The major developments of the past decade have been the increase of interest in medical and biological study of specific clinical types on the one hand, and increasingly extensive psychological study of, and provision for, the numerically and socially more important high grade group on the other.

CLASSIFICATION

Three systems of classification of mental defectives are in common use at present. (1) Psychological and social classification as to intellectual grade or level (idiot, imbecile, moron or feeble-minded, and borderline). (2) Medical classification as to clinical type (familial, mongolian, cretin, hydrocephalic, etc.). (3) Etiological classification (hereditary and acquired, or primary and secondary, or, more recently, endogenous, exogenous and mixed). Institution populations are ordinarily classified as to level and clinical type, and occasionally as to etiology. The relative clinical importance or scientific value of the different classifications varies with

the condition and the problems connected with the particular case.

Classification according to level. Definitions of the *idiot*, *imbecile* and *moron* levels in terms of mental ages were formulated by the American Association for the Study of the Feeble-minded in 1910, with designation of I.Q. limits for each group added in 1920. Until 1934 the Stanford Revision of the Binet Scale (1916) was specified, with 16 years as the divisor for chronological ages beyond 16. No mention of any specific test appears in the 1941 edition of the Statistical Manual for Institutional Use, but the following definitions are given:

"An *idiot* is a mentally-defective person usually having a mental age of less than 3 years or, if a child, an intelligence quotient of less than 20."

"An *imbecile* is a mentally-defective person usually having a mental age of 3 years to 7 years, inclusive, or, if a child, an intelligence quotient from 20 to 49, inclusive."

"A *moron* is a mentally-defective person usually having a mental age of 8 years or upwards, or if a child, an intelligence quotient of 50 or more. As a rule the upper limit for a diagnosis of mental deficiency should be an intelligence quotient of 69, but this limit should not be adhered to in cases where medical, social and other factors clearly indicate that the patient is mentally defective. The term 'moron' includes all mental defectives above the grade of imbecile."

In England the definitions of the idiot, imbecile and moron levels, legally established by the English Mental Deficiency Act of 1927, are based upon social competence. According to these definitions:

Idiots are "persons in whose case there exists mental defectiveness of such a degree that they are unable to guard themselves against common physical dangers."

Imbeciles are "persons in whose case there exists mental defectiveness which, though not amounting to idiocy, is yet so pronounced that they are incapable of managing themselves or their affairs, or in the case of children, of being taught to do so."

The *feeble-minded* are "persons in whose case there exists mental defectiveness which, though not amounting to imbecility, is yet so pronounced that they require care, supervision, and control for their own protection or for the pro-

tection of others, or, in the case of children, that they appear to be permanently incapable by reason of such defectiveness of receiving proper benefit from the instruction in ordinary schools."

Thus the definitions in use in the United States are primarily in terms of standardized measures while the English definitions are in terms of important everyday adaptation to the physical and social environment. At the two lower levels the criteria parallel each other closely; at the upper level both are more flexible and more open to local interpretation.

Within each level the range of mental ability is large, the terms high-grade and low-grade being frequently employed to indicate relative position within a particular level. It follows that a low-grade imbecile and high-grade idiot may be more nearly similar in mental capacity than two imbeciles of whom one is low-grade and the other high-grade. When the degrees or levels of defect are thought of as arbitrary subdivisions of a continuum, the tendency to establish artificial distinctions is less obscured. Furthermore, it has repeatedly been shown that groupings based solely upon the composite test score of a Binet examination do not entirely correspond to groupings based on other equally reliable psychological test measures. Classification according to level is a useful tool but it is not a satisfactory basis for comparative scientific studies, although in the past it has been frequently so employed.

For practical purposes a rough classification into low-grade defectives and high-grade defectives has long been used. The former group includes those requiring custodial care, viz., all idiots, nearly all imbeciles, and some low-grade morons who, because of severe physical disabilities, or great emotional instability, are unable to function at their intellectual level and require long-term or permanent institutionalization. The high grade defectives include those with less severe intellectual subnormality in combination with social inadequacy or clinical conditions not sufficiently serious to necessitate long institutionalization but often requiring prolonged supervision, specialized training, or temporary institutional care. A small percentage of those who are intellectually "moron" or "borderline" moves in and out of institutions, constituting a group of "marginal" defectives whose need for supervision or care largely de-

pends upon, and varies with, the conditions of the families and communities in which they live. Some have questioned whether this high-grade group should ever be classified as "defective." Goddard, who introduced the term moron, suggested that the upper limit of feeble-minded had been placed too high and that the "real limit" might better be a mental age of seven years than twelve years. "It is pretty generally accepted that no amount of training of the best kind we know, can make a person of only seven-year mentality capable of filling even a small place in the social group. This would mean that there are two groups of the feeble-minded, not three. There are idiots and imbeciles. The morons comprise that large group of people whom we recognize as of dull intelligence who never live sumptuously or manage themselves or their affairs with a high degree of prudence, but nevertheless do manage themselves; and, if carefully and wisely trained, are not a burden in the community." Any "limit" in terms of a single criterion will undoubtedly always prove indefensible however necessary for social and legal purposes some specification of limit may be.

Classification according to Clinical Type. Classification of mental defectives as to clinical type is determined largely by physical characteristics, family history, or medical and laboratory findings. Though receiving little attention from psychologists, clinical classification is increasing in scientific importance as clinical conditions are more intensively studied. Among the more frequent identified types in approximate order of incidence, according to institution admissions in New York State, are: *familial mental deficiency; mongolism; post-traumatic conditions; post-infectious conditions* (including both post-meningitic and post-encephalitic amnias); *with developmental cranial anomaly* (including microcephaly, oxycephaly, and hydrocephaly); *with other organic nervous disease; and due to epilepsy.* Idiots savants are sometimes considered a clinical type. Cases for which no clinical classification can be made are commonly called "*undifferentiated.*" This is the largest single classification, and includes nearly half the institutionalized defective population. Textbooks on mental deficiency and the medical literature give detailed descriptions of the known clinical types though only about 25 per cent of the institutionalized defectives (and those chiefly

in the low-grade groups) can be classified as other than "familial" or "undifferentiated."

Also of clinical importance and in addition to specific clinical types, there are partially recognized and explored relationships between mental deficiency and neuropathic ancestry, convulsive disorders, syphilis, glandular dysfunction, and special sensory or motor defects, all of which may occur independent of, or in association with, low intelligence. In the case of a particular defective individual, as well as from the standpoint of research, the importance of clinical classification is proportional to the available knowledge regarding the clinical type in which the individual is classified. For psychology the classification into clinical types will become increasingly important as more refined methods for study of mental functioning, together with more adequate knowledge of underlying pathology and deviating organic conditions, provide opportunity for exploration of possibly concomitant processes.

Classification According to Etiology. The earlier classification into *hereditary* and *acquired* mental deficiency was supplanted by Tredgold's introduction in 1908 of the terms *primary* and *secondary*, the former designating all cases of mental defect "the cause of which is intrinsic, endogenous, or germinal," the latter designating "those cases which are extrinsic or exogenous in origin, that is to say . . . the result of some adverse factor of the environment acting upon the offspring at any stage from the fertilization of the ovum up to the time at which the development is complete." This classification has been useful especially for prognosis and provisions for training and care. In general, secondary or exogenous amentia is more frequent in low-grade cases and primary or endogenous amentia more frequent among high-grade cases. Strauss and Werner have recently made use of a classification into *endogenous*, *exogenous*, and *mixed groups*, strictly defining the first two groups for purposes of scientific study. Lewis, in England, has proposed a classification into *pathological amentia* and *sub-cultural amentia*, the latter comprising cases that represent extreme deviation at the lower end of the normal distribution curve of intelligence, the former, cases due to pathological conditions. This also, in effect, corresponds roughly to a grouping into low-grade and high-grade cases. The classification is not widely used and has

been criticized on the ground that a number of cases can be included in both categories.

INCIDENCE, CAUSATION, AND CONTROL

Questions as to incidence, causation and control of mental deficiency have been approached through study of accumulating records of identified mental defectives and their family histories, through population surveys, and through scientific study of specific clinical types. There are very few conclusive answers, but specific problems have become more clearly defined as the heterogeneous character of the field has been increasingly recognized.

Incidence. Surveys made in the United States and the British Isles to ascertain the over-all incidence of mental defect have given varying figures. The differences are attributable to differences in methods of securing data (questionnaires, house to house visits, school records or census reports), in criteria of defect (test results, academic retardation, institutionalization), and in inclusiveness or representativeness of the population studied. In 1926 Lewis concluded, on the basis of a survey in England and Wales of a population of 662,880, that the incidence of mental defect was 8.57 per 1,000. This was nearly double the estimate from a similar survey in 1904 and higher than the figures given by state and local surveys of the same period in the United States which varied between 3.4 and 7.3 per 1,000. The United States draft boards of World War I reported that 9.24 per 1,000 were thought to be mentally defective. Studies to determine racial or national differences in incidence of mental defect have been inconclusive except for indication that the occurrence of low-grade intellect is more common among Negroes than among whites. Mental defect is regularly found to be slightly more prevalent in rural than in urban areas. At lower levels there is a slight predominance of males, at higher levels, of females. A conservative estimate for over-all incidence of mental defect among the adult population of the United States is 1 per cent.

Surveys of younger age groups show a higher incidence of mental defect than do surveys of adult populations, due in part to the relatively early death of many defectives, and in part to differences in criteria of defect at different ages. MacMecken in a careful study of the intelligence of a representative group of ten-year-old

Scottish children found 1.26 per cent with I.Q.'s below 70. A statewide survey by the Connecticut State Department of Education in 1940 reports 2.5 per cent of the children between four and sixteen years, exclusive of those in institutions, to be "mentally handicapped to the extent that special educational provisions are necessary to meet their needs." General estimates of defectives in the public school population place the incidence between 2 per cent and 3 per cent.

Within the mentally defective group the incidence varies inversely with the degree of defect. Of all defectives not more than 5 per cent are idiots and less than 20 per cent are imbeciles. The remainder are morons. As previously stated, incidence varies also with clinical type. Tredgold estimates the incidence of mongols at all ages at 5 per cent, but considers that of children diagnosed as mentally defective before one year of age 50 per cent are mongols, and of those diagnosed before five years of age 25 per cent are mongols. Many clinical conditions, including those due to recessive genes, are of rare occurrence. For example, Jervis identified 200 cases of phenylpyruvic oligophrenia after examination of 20,000 mental defectives. Incidence is highest for "familial" mental deficiency. Over 30 per cent of the defectives admitted to the New York State institutions are so classified and the percentage of the total defective population falling within this group would be far higher.

Causation. Early studies by Goddard and Davenport of the familial incidence of mental deficiency led to the conclusion that defective germ plasm was responsible for two-thirds of the cases. More recent estimates give figures for the incidence of primary mental deficiency varying from 75 per cent to 90 per cent (Tredgold, Wildenskov). Penrose is more conservative and reports that careful study of 513 institutional cases showed that only 29 per cent could be unquestionably attributed to genetic causes, and only 9 per cent to secondary causes. The remaining 62 per cent he considered "unclassifiable" due to the difficulty of "extricating from one another" the effects of environment and heredity. During the past decade interest in causal factors in mental deficiency has led to accumulation of data from many sources.

Important known causes of secondary or exogenous mental deficiency include encephalitic and meningitic infections, birth trauma, epi-

lepsy, syphilis and sensory deprivation. Mongolism is generally considered exogenous though the causal factor is not established. The probability of mongol births increases steadily with advancing maternal age (Bleyer, Myers, Benda). To establish secondary, environmental, or exogenous origins of defect, it is necessary to investigate such conditions as: ordinal position at time of birth; relationship of births of defectives to miscarriages and still births; presence of syphilis or alcoholism in the parents; diseases of the mother during pregnancy; birth trauma; and post-natal disease or trauma.

To establish endogenous origin of mental defect requires investigation of the incidence of defect in relation to consanguinity of parents, and the distribution of the condition among ascendent and collateral relatives. Understanding of the mechanism of inheritance has been furthered by studies of twins (Rosanoff, Kallman), study of ratio of defective offspring of specific clinical types to non-defective siblings (Sjögren, Penrose, Jervis), and comparison of the intelligence of siblings of children of different intellectual levels (Roberts). Statistical investigation of data has been used to study such various possible mechanisms of transmission as dominant, complementary dominant, sex-linked, recessive, or multifactor, genetic determinants. It has been found that phenylpyruvic oligophrenia, gargoylism, and amaurotic idiocy (both juvenile and infantile forms) appear in accordance with the expectation for a Mendelian recessive. Cases which are clinically classified as familial, either on the basis of recurrent defect for successive generations or a high incidence of mental defect in the offspring of known defective parents, are considered hereditary even though no mechanism of transmission has been established.

Either or both endogenous and exogenous factors may be causal in cerebro-spastic diplegia or paraplegia. This condition was long considered by some authors to be a result of birth injury alone. Cretinism, due to thyroid deficiency, may result from hereditary deficiency. It may also occur with or without environmental lack of iodine in the diet or with some pathogenic water supply. Hydrocephaly, which may follow an infectious process, is classified clinically with microcephaly as a cranial anomaly, though there are indications that microcephaly, in some instances at least, is of endogenous origin. In an undetermined proportion of cases,

defect of secondary origin has been superimposed upon an originally endogenous defect.

Control. In the field of mental deficiency "control" is used as synonymous with "prevention." Since the condition may result from a variety of causal conditions and circumstances, it follows that no single general program for control is indicated. In exogenous conditions, attempts at control must be directed to the specific causal factor. More adequate understanding and treatment of encephalitic or meningeal infections and other febrile conditions would undoubtedly reduce the incidence of a specific group of cases. Improvement in obstetrical practices and in ante-natal and early post-natal care would bring about further reduction. According to an estimate by Hogben, the number of mongols would be reduced to one-fourth the present number if childbearing were restricted to the period between twenty and thirty years. The largest single clinical group, familial mental deficiency, would be relatively unaffected by the foregoing measures. Cases of familial origin are less frequent among low-grade than among high-grade defectives. Moreover, since practically all idiots and many of the imbecile group are biologically sterile, the problem of transmission by these individuals is negligible. It is in relation to the high-grade and borderline defectives, where the familial type occurs most frequently, and among whom are found a considerable number of individuals "feebly-inhibited" as to reproductive drive, that the question of control is most often raised. Programs advocating sterilization have led to the enactment of sterilization laws in a number of states. Four states enacted such laws prior to 1910 and by 1940 sterilization had been legalized in thirty states. The laws differ widely in latitude, and in only twenty states had there been more than three hundred official operations prior to January 1, 1945. The State of California up to that date had sterilized 4,968 mental defectives and five other states have records of over one thousand operations each. Delaware and California rank first in the number of operations per 100,000 population. An alternative program has proposed segregation in institutions or colonies of mentally defective women of the familial type during the child-bearing period. This has been shown to be impractical because of the expense involved. A number of states, among them South Dakota, Massachusetts and Utah,

have undertaken state-wide registration of mental defectives, and some states have enacted laws prohibiting marriage of mental defectives. There is increasing social approval of efforts to identify families having records of a high incidence of mental defect in successive generations. Selective sterilization or segregation in extreme cases is widely advocated and frequently practiced. In general, however, geneticists and eugenicists are in fair agreement that the mechanisms of human heredity are as yet too little understood to warrant the introduction of any far-reaching program for genetic control of mental deficiency.

TREATMENT, CARE, TRAINING, SUPERVISION AND GUIDANCE

Mental deficiency as a condition is not a biological unit or entity. It consists in a lack of potentiality for development. Of itself it is not a disease. Except in cretinism, there exists no specific treatment or "cure." In cretinism the administration of thyroid, especially when begun at an early age, stimulates physical development, increases alertness, and in certain cases measurably promotes mental development. Cretins differ markedly, however, as to response to medication. Medical experimentation with other clinical conditions continues to some extent. Attention now is being directed chiefly toward providing care for the low-grade defectives, and training that will facilitate adjustment of those of higher grade, in the community if possible, and in institutions if necessary.

Low-grade defectives are more often institutionalized, but since institutions in the best equipped states provide for only one in ten of the defective population, the majority of the low-grade cases and nearly all high-grade cases remain in the community. Institution provisions for both groups have increased steadily; in New York State, for example, from 8.3 per 100,000 of the general population in 1884 to 109.7 per 100,000 in 1939. Provisions in different sectional areas of the United States vary greatly. Zubin, studying regional hospitalization rates for defectives and using the rate for the entire United States as a basis for reference found indices well above 100 for the New England, middle Atlantic, and north central states, whereas for the south central and the south Atlantic states the highest index was 53.7 and the lowest 39.5. The relative proportions of high-grade and low-grade

cases within any institution depend upon admission policies of the institution, community or state. In New York State about 50 per cent of the admissions are from the moron and borderline groups. The age difference between low-grade and high-grade defectives at the time of admission is indicative of the difference in problems they present. Of 965 consecutive admissions to New York State institutions nearly 60 per cent of those classified as idiot and over 40 per cent of those classified as imbecile were admitted at ages below eleven years. Of those classified as moron, 65 per cent were admitted at ages between ten and twenty years.

Institutions afford opportunity for observation of the general competence of the inmate population in a simplified and relatively standard environment. It has been found that idiots, except those of lowest grade, gain in ability to help themselves in eating and dressing if subjected to persistent training. The higher grade imbecile can learn to perform simple, routinized tasks under supervision. In many institutions the imbeciles contribute to the institution maintenance. Where there is a farm the boys assist in clearing land, feeding cattle, planting and harvesting vegetables. The girls learn bed-making, preparing of vegetables, and simple cleaning in kitchens and cottages. Habit training, if begun at an early age will establish personal orderliness, cleanliness, and simple forms of social behavior in all but the unstable or poorly adjusted members of the group. Academic achievement is negligible. Those who may be taught to recognize a few printed words can never progress to the point of making use of their accomplishment.

Work with the high-grade and borderline defective is rapidly becoming a distinct and specialized field. Problems presented by this group are of concern to school systems, social agencies, the field of industry, the courts, and institutions for delinquents and for lower grade defectives. The adjustment difficulties of the high-grade defective, who differs from the average individual in his greater need for special training and supervision have become the focus of a considerable area of clinical psychology. Here the work of the clinical psychologist includes: diagnosis of mental defect, determination of specific abilities and disabilities, making of recommendations with regard to admission to special classes, the investigation of

opportunities for special training, counselling of the individual defective and/or his parents, and possibly arranging for commitment to an institution.

Training of the high-grade defective. As the range of possible adjustment and maladjustment become greater, the potential effectiveness of environmental conditions is correspondingly increased, and the needs for training, supervision and guidance become more varied and insistent. Large numbers of high grade defectives brought up in fairly well-regulated and understanding homes in which they are given a measure of social protection, develop into self-respecting members of the community. They are able to perform simple but necessary tasks and achieve a fair degree of self direction. They ask for, and are willing to accept, advice. Many maintain themselves under ordinary conditions. It is because of those who fail to make adequate adjustment that there have been established diagnostic clinics, special classes, pre-vocational or occupational training, and other provisions for assisting the large number of morons and borderline defectives who remain in the community.

The educational requirements of this group differ greatly from those of the lower grades. Their possible academic accomplishments are more extensive. The fundamentals of reading and simple arithmetic can be used to some degree and the social demand for this achievement is recognized by them. Education at the elementary grade level should therefore emphasize development of the rudimentary skills. The modern school system, in addition to classes for slow-learning pupils, provides special classes for pupils of the borderline and high-grade defective groups. Such classes meet only the need of those of elementary school age. The high age limit for compulsory education now in vogue has aggravated the difficulties of the adolescent high-grade defective who is kept from employment by labor legislation and from profitable use of his time at school by his inability to enter high school or to find suitable training in the elementary school program. Progressive educational systems in several cities have recognized the need for an effective and practical educational program for the older pupils of the moron and borderline defective groups and have initiated educational and research programs centered about pre-vocational

and occupational training for subnormal pupils through the high school years.

COMMUNITY PROGRAMS FOR SUPERVISION AND GUIDANCE

Whatever his school or institution training, the high-grade defective ultimately becomes a member of the adult community with its occupational and social requirements. Until recently communities have taken little responsibility for the adjustment problems of their defectives. In large centers opportunities for vocational guidance and training have been occasionally available through the efforts of social agencies. In general, the adjustment of the individual defective depends upon the interest of his family and upon chance factors. In a rural community he may become a farm helper. In an urban environment he may secure a simple industrial or factory job or work as an unskilled laborer. Many defective girls enter domestic or laundry services, or take simple industrial jobs. Studies of mental age levels in industry have shown that workers with mental age levels as low as eight years can be successfully employed. During World War II it was found that some drafted men with mental ages of nine and ten years could be utilized in the service forces. Since work opportunities vary with general economic conditions, the defectives are able to find employment when labor is scarce, but when times are hard they are out of work and become dependent. Their limited resourcefulness and slow adaptation to new conditions augment the burdens of the community.

An additional problem is the incidence of delinquency and crime among the high-grade defectives. In some cases this is due to psychopathic tendencies or clearly developed antisocial trends but more often it is a result of the suggestibility of defectives which invites exploitation by more intelligent criminals, or by organized gangs of delinquents. However, the contribution of the mentally defective population to delinquency and crime is not great, since it has been estimated that not over ten per cent of delinquents are mentally defective, though a much larger percentage is "subnormal." In England a special classification "moral defective" has been established, but no comparable term is used in the United States. In a particular case the development or non-development of delinquency is apt to depend upon the degree

of protection which is afforded by the family or the community, or, lacking this, by some institution. Many unmarried girls between the ages of fifteen and twenty-five become pregnant and finally habitual delinquents because they lack adequate family support or supervision. Many boys aged fifteen to twenty become members of organized delinquent gangs for the same reason. Increasing recognition of the drain upon the economic and social resources of the community due to the high grade defective and borderline groups has led a number of states within recent years to develop community programs for dealing with the problems presented by this segment of the population. The programs vary in the extent to which they call for an integration of such community resources as educational systems, private and public agencies, and institutions. In some states emphasis has been placed upon central registration of defectives and prevention of marriage. Massachusetts and several western states maintain statewide supervisory and advisory clinical services. In other states emphasis is upon development and utilization of local agencies.

CHARACTERISTICS OF THE MENTALLY DEFECTIVE

Since various and discrete conditions are included under "mental deficiency" only limitation in intellectual ability and social competence is common to all defectives. Within the mentally defective group, psychological characteristics, incidence of pathological conditions, and physical characteristics vary with mental level and with clinical type. For all subgroups (except within the idiot level and for certain clinical entities for which a few fairly specific characteristics have been established) both the range of individual differences and the degree of overlapping with other groups, are large. Although it is generally considered that "feeble-mindedness is indicative, not only of mental malfunctioning, but also of physiological malfunctioning," attempts to establish specific relationships between physical, physiological or pathological conditions on the one hand, and psychological characteristics on the other, have had little success.

PHYSICAL FEATURES AND PATHOLOGICAL CONDITIONS

Recognition of specific physical characteristics and pathological findings has largely determined the identification of clinical types of

mental deficiency. However, even those clinical types within which there is greatest homogeneity show individual variation and in no type are all gross characteristics of the type invariably present. Furthermore, no features except certain biochemical alterations and neuropathological conditions have been demonstrated as exclusively coexistent with any specific clinical type. An alteration in metabolism resulting in excretion of phenylpyruvic acid in the urine of the patient, is the identifying characteristic of phenylpyruvic oligophrenia (or ketonuria), a clinical type first described in 1934. Accompanying this bio-chemical condition are anomalies of the motor system and pronounced mental defect. The latter, however, covers a considerable range, two-thirds of the identified cases being idiots, and one-third imbeciles. Disturbances in lipid metabolism found in gargoylism, amaurotic familial idiocy, and related types having a similar neuropathologic picture are associated with clinical manifestations that differ for the different conditions. In gargoylism there are disturbances in skeletal growth, mental defect is not always present, but if present, is apparent from birth, convulsions rarely occur, and deterioration is not characteristic. In juvenile amaurotic idiocy, on the other hand, skeletal changes have not been observed, mental development appears normal up to five or six years, convulsions are invariably present, and there is progressive deterioration, reaching profound idiocy within a decade.

Mongolian defectives, studied extensively since the condition was first described by Langdon Down in 1866, and constituting a numerically important group, present a relatively homogeneous combination of physical features. Among these are commonly found: a narrow, oblique, palpebral fissure; epicanthus; microbrachycephalic skull; small, broad, depressed nose; small, round mouth; large, often protruding and fissured tongue; small, broad, stubby hands; widely separated big toe; extreme laxity of the joints; disturbances of dentition; and delayed puberty. Disorders of the nervous system are not conspicuous, but autopsy findings have shown defective development of the brain and pathology of the hypophysis. Brouseau, reporting on 206 cases, found approximately two-thirds to be imbeciles and one-third idiots. Mongols show unusual susceptibility to respiratory disease; congenital cardiac anomalies,

as well as other structural deviations are frequent. Cretins, constituting perhaps the earliest recognized, and one of the most widely studied clinical groups, like mongols, show greatly retarded physical development but they do not show the markedly delayed and irregular dentition that is characteristic for the mongol group and they lack many specifically mongoloid features. Other clinical types have less distinct patterns of physical and pathological characteristics, the familial mental defectives showing greatest heterogeneity of physical features and least frequent occurrence of pathological conditions.

For both physical characteristics and pathological conditions, relationships to mental level or degree of defect are less specific than relationships to clinical type, though frequency of abnormalities increases with decrease in mental level. Thus few idiots are entirely without physical or neurological defect and some present a veritable museum of abnormalities. Developmental anomalies of special sense organs and of the nervous system are frequent. Physical stigmata, lack of symmetry and of effective coordination are common. In both stature and weight idiots are below the non-defective population. Their life expectancy is less; the average age of idiots in New York State institutions at time of death being 19 years, and of imbeciles, 31 years. In the imbecile group incidence of defects and malformations is more variable; many approximate the non-defective population in appearance. The moron and borderline groups, excepting cases of specific clinical type, are relatively free of pathological conditions, and of physical or neurological defects.

PSYCHOLOGICAL CHARACTERISTICS

The first attempt at careful description of the psychological characteristics of the feeble-minded was made by Binet who undertook comparative studies of mental abilities of idiots and imbeciles in psychological functions ranging from rudimentary processes to the highly complex activities involved in abstraction, judgment, reasoning, and language. Binet demonstrated that such a hierarchy corresponds roughly to levels of mental ability, the entire range of abilities being present in the non-defective individual, whereas in individuals of the mentally defective group the more complex processes are limited, and may be absent if the defect is severe. In a

defective individual, limitation in function throughout the hierarchy of psychological processes is roughly related to the degree of defect. The psychological behavior of an imbecile, therefore, is less like that of an average individual than is the psychological behavior of a moron. At all levels of mental defect the more complex processes are most severely limited, the more rudimentary (as, for example, simpler forms of perception and sensory-motor behavior), are less limited. Thus two defectives, one of moron and one of idiot level, will differ far less in ability to avoid collision with a chair, than in ability to describe a picture. Within this general scheme there are wide individual differences, with examples, at every mental level, of defectives whose abilities are relatively even, and of others whose performance in one or several areas of mental activity may be far inferior or far superior to their general capacity. The idiots savants, having unusual memory or musical skill or facility with number combinations (sometimes far in advance of the ability of the average individual) together with severe mental deficiency in all other areas, present extreme examples of the possible unevenness in mental abilities which may be found within a population of mental defectives.

The idiot is least representative of the human species. Though most severely limited in range of behavior this group is far from homogeneous, except in regard to the absence of the more complex mental processes. Motility patterns range from a generalized hyperactivity to extreme limitation of movement. Stereotyped activities such as rocking, peculiar sucking, clucking noises, or picking at parts of the body, are common, and are similar to those observable in deteriorated psychotic patients or in caged chimpanzees. Postural control is of variable adequacy but good coordination is infrequent. A number of idiots learn to walk, but their gait is clumsy. Many learn to sit and others crawl or hitch themselves about. Some establish sphincter control. Vocalization differs; many are noisy but unintelligible. A limited number learn to pronounce one or two words fairly intelligibly. Because of technical difficulties little reliable data regarding the sensory acuity of idiots is available, though observed responses to taste, olfactory, auditory, and visual stimuli give indication that unevenness in the sensory fields is common. Capacity for sustained, controlled at-

tention is lacking, and brief, spontaneous attention given to external stimuli varies greatly, not only from one individual to another but also from time to time for the same individual. There is also great variation in social interest and responsiveness, a limited number of idiots showing no sign of recognizing individuals, whereas others show decided social preferences and develop strong attachments, even exhibiting solicitude for the welfare of a particular companion or cottage mate. Physical aggressiveness, apparently unpremeditated, such as biting and striking are not uncommon within an idiot group, but these manifestations are usually limited to a small number of individuals, and are for them either habitual or recurrent. Such explosive behavior, like stereotyped activities, may appear at times of general excitement, or may occur in the absence of external stimulation, possibly as a mechanism for energy or tension release.

Imbeciles as a group show less limitation of psychological function and greater awareness of their environment than idiots. Ability to attend to personal wants, development of habits, simple speech, social discrimination, responsiveness and interest, are all present in varying degree. Speech defects are present in more than 50 per cent of all imbeciles and are not remediable. Memory for specific material may be highly developed and learning of a simple sort is present throughout the group, but capacities for generalization, abstraction, judgment, and problem solving are limited. The range of emotional behavior in some individuals seems to approximate the emotional behavior of the average non-defective individual. Sexual interest and behavior vary within the group but are less frequently noted, and less marked than among those of moron level.

The school-age "moron" differs from the child of the "borderline" or "dull-normal" categories in the over-all account he gives of his mental ability in standardized test situations, and in his lack of ability to meet the academic requirements of the upper grades of the average school system. Up to the third or fourth grade many morons make fair progress, but when presented with requirements which go beyond the mechanics of reading to the comprehension of material presented by the printed page, beyond simple enumeration to the mastery and use of numerical relationships, beyond simple, direct

communication to imaginative and symbolic dealing with the problems of the social environment, their inability becomes readily apparent. In some cases the inability appears as a general retardation in all areas of mental functioning, in others, as a marked inadequacy in some particular area, such as verbal comprehension or social judgment. Speech defects are more frequent than among non-defectives, and at the moron level remedial procedures are effective. Detection of adult morons is more difficult than in the school-age group since casual observation is insufficient, and such individuals are seldom placed in standardized situations.

PSYCHOLOGICAL RESEARCH

Many of the psychological studies in the field of mental deficiency have been directed toward immediate clinical needs rather than toward basic psychological problems. Of the three pioneers in the field, Itard and Binet (especially the latter) were concerned more with theoretical considerations than with practical applications. Early studies in the United States, however, were influenced by Seguin, whose interest was almost exclusively in the clinical aspects of his work. Although the tests of Binet and Simon were quickly adopted in America, little attention was given to the psychological studies which preceded and accompanied the test development. Early work in this country was thus directed toward practical questions relating to the value of tests, whether for determining potential academic achievement, for selection of those who required institutional care, or for classification of institution populations. Many studies were concerned with determination of the validity and reliability of the measures. This preoccupation with test application obscured for many years more fundamental questions as to the nature of intelligence and of mental defect, which Binet had originally set out to investigate.

Recognition of limitations of the Binet Scale, especially its dependence upon verbal and symbolic material, led to development of additional measures: the Porteus Maze test, the Kohs Block Design test, various other performance tests and scales (Healy, Pintner-Paterson, Arthur Point, Kent-Shakow) and the Vineland Social Maturity Scale. These were designed to provide either supplementary, or more accurate, clinical or diagnostic instruments. The field of mental

deficiency became a proving ground, not only for successive translations and revisions of the original Binet-Simon Scale, but for other measures, many of which were standardized, in part, by establishing correlations with Binet test results. The multiplication of tests led to questions regarding selection of tests and interpretation of divergent test scores, to more intensive study of individual cases, and to increasingly controlled investigation of the clinical significance of specific patterns of test performance.

As the number of tested mental defectives increased, other clinical problems claimed attention. Studies were made of concrete performance abilities, of "social competence" as distinguished from "mental level," of the effect of highly specialized programs, and of the later community adjustment of those trained in special classes or released from institutions. Current information and practice in the training and counselling of the higher grade defective population have depended largely upon these clinical studies.

No clear line of demarcation can be drawn in this field between clinical studies and non-clinical research. In the development of the Binet Scale the need for a clinical instrument was closely related to interest in the psychological problem of intelligence. Goddard's investigations of the psychological functioning of the subnormal, like Binet's studies, extended beyond specific clinical aspects of mental deficiency. Kuhlmann's annual re-examination of 639 defective subjects over a ten-year period, contributed to general psychology as well as to the clinical field. His data show that the rate of mental development depends upon the grade or level of intelligence, that the rate decreases with age for all grades, that for all groups the mental age ceases to increase between fifteen and eighteen years and that the mental growth curve of the idiot ceases about three years earlier than for those of borderline intelligence. More recent studies of groups carefully selected on the basis of clinical type or of etiology have shown that Kuhlmann's statistical findings, though accurate as to general trend, are not invariably valid for prediction of development for an individual defective, since clinical type, etiological condition, and environmental circumstances all influence the curve of individual development. Exogenous cases, for instance, often show a drop in mental age. Results of other early studies are no longer taken at face value

and their theoretical implications are being questioned.

During the past decade psychological research in mental deficiency has partly broken away from its preoccupation with investigation of "intelligence." The range and variety of both problems and methods have been greatly extended. Experimental procedures from the fields of child and animal behavior and from physiology have been used in exploratory studies. The objectives of investigations have been more clearly defined and the experimental subjects more carefully selected. These recent studies are too numerous, too diverse, and too largely preliminary in character to justify detailed report or to warrant attempt at the present time to evaluate their ultimate contribution. A few have been selected for mention as illustrative either of recent trends in investigation or of careful attention to experimental controls.

Werner and Strauss, in a series of studies using various tests and experimental methods, have compared the psychological performance of "brain-crippled" subjects (having "a brain lesion acquired by trauma or inflammatory process, before, during, or after birth") with the performance of subjects of the same mental level from the endogenous (familial) group. In contrast to the latter, they find that subjects of the exogenous group show disturbances of organization in sensory-motor, perceptual and thought processes, with tendencies to pathological perseveration, more frequent "incoherent" responses, greater distractibility, and a higher frequency of "animistic" responses suggesting "a pathologically altered relation to the outside world." In addition to their clinical significance these studies approach theoretical problems of mental organization.

A number of comparative studies have been reported. Rethlingshafer used interrupted tasks with various conditions of interruptions in a comparative study of college students, normal school children and mentally defective subjects and found little difference in tendency to resume activities though barriers to resumption had greater effect upon defective than upon normal subjects. Gardner has studied the learning of low-grade aments (idiots and imbeciles), using experimental conditions previously used with various domestic animals (horses, cows, and sheep), and found a quite similar rate of decrease of errors, though the aments were less

stereotyped in their errors than animals. Studies of the relative influence of mental level and life experience in determining generalizing ability, concept formation, vocabulary and development of thought processes, based on comparison of groups of mentally defective subjects at given mental ages with selected differences in chronological age have shown the importance of mental age in the development of complex mental functions.

A few exploratory investigations have been concerned with problems of "personality differences" in mental defectives. Porteus, in discussing the maze test emphasized its value in affording opportunity to detect "the impulsive and headstrong with little tendency to preconsideration, the nervous and excitable, the irresolute and easily confused, the impractical, the dreamy and dependent, the over-confident and over-inhibited, or children too self-determined to heed or follow instructions accurately." But, though recognized clinically as characteristics frequent among defectives, until recently there has been little research attention to these differences. A few studies have investigated tendencies to perseveration, response to frustration, and behavior in situations requiring social participation. Abel has devised methods for study of inter-personal relationships and dominant behavior of institutionalized defectives. A study of major emotions in mentally defective subjects was made by Morrison who concluded that emotional development is a complex process not definitely linked with physical or physiological maturity. The Rorschach procedure has been more widely used. In addition to confirming other data regarding the stereotypy of the mentally defective individual and his inability to generalize and to integrate elements of experience, the Rorschach results have indicated strong reaction to color, wide variation among defectives in emotional control, and in patterns of perceptual behavior. These differences in Rorschach performance are considered indicative of differences in personality organization. Many areas remain relatively unexplored. Doll has listed some of these, including motor development, maturation, learning, and motivation. Speech and language and their use by defectives of different levels has had little attention.

There is as yet in the field of mental deficiency no comprehensive psychological research program comparable to those in other fields of

psychology, as, for example, in the studies of animal behavior. Thus there has been no controlled, systematic investigation of specific psychological problems comparable to the studies of perception in animal or normal human subjects, nor can there be found any series of studies devoted to the development of specific methods comparable to the time-sampling studies of young children. This may be accounted for in part by the conditions under which psychologists in this field have had to work, in part by the sporadic and sometimes incidental nature of their interest, and in part by the generally limited appreciation of the research material which the field affords.

Emphasis continues to be focussed upon clinical problems. Largely as a result of the long-continued efforts by Doll, Goddard, Hegge, Porteus, and others, there is increasing interest in clinical research and steady improvement in the quality of clinical studies. Clinical facilities for mental defectives have been improved in many states. Recognition of the challenge offered by the somewhat simplified mental organization of the defective subject is indicated by current suggestions of the need for basic research. It would be possible today to take exception to the statement made by Binet that those working with the mentally deficient "have never examined them from the point of view of questions which their mental state raises in regard to modern psychology," nevertheless, in many respects, the statement is nearly as true as in 1908 when it was written.

FETAL LIFE, BEHAVIOR DURING.

—Anyone who is interested in what adult human beings do or can do is almost certainly also interested in the antecedent steps by means of which such behavior has developed. The study of fetal behavior is a study of the first part of this long and important growth sequence. The investigation of fetal behavior involves a consideration of all aspects of the development of the activity of the young organism from the time of conception until birth.

Until fairly recently the standard writers on child psychology thought of this field of knowledge as beginning at birth. Now it is recognized that one who would understand the background of man's early behavior must consider human responses made during prenatal life.

After fertilization the morphological development of the young organism begins. The first period of this continuous growth process is ordinarily spoken of as germinal. It typically lasts for two weeks. The next period is thought of as embryonic; this stage ordinarily is considered in man to last until about the sixth week. The final stage preliminary to birth is described as fetal and involves the period from the sixth week to birth. In every consideration of the growing human individual before birth it is important to remember that the student must at all times deal with a living organism which is maintaining itself in its environment. At every moment from fertilization to birth the new growing and living individual reacts as it does to its environment because of its own intrinsic make-up and because of the world of substances and energies in which it is existing.

As one traces back many characteristics of behavior as seen in the adult human individual, it is often very instructive to see what the characteristics in question were preceded by. When this *long-section* view of development is taken, it is found that, while there are certain dramatic and sudden *emergence phenomena* in behavior, in general it is possible to see exactly what the antecedents of each step have been. A recogni-

tion of the continuum of development is important for anyone who would understand fully the later capacities and characteristics of the organism.

The study of mammalian fetuses has clearly shown that the first gross movement of any organized cell mass or primitive organ system is the rhythmic beating of the heart. This rhythmic contraction of primitive heart cells, which may be thought of as antecedent to true heart action, begins in the human organism during the third week. In other words, this first activity of the specialized cell groups begins at about the same time set as marking the termination of the germinal period in the human fetus. In most work on the development of behavior the beating of the primitive heart cells is not considered to mark the onset of what is called true behavioral life. This distinction is made because it is recognized that these cells are beating as a result of their own metabolic processes, which are maintained in an environment made up of the fluids and cells of the organism in which the heart cells exist. Before true overt responses of the organism occur which result from muscle contractions which are under nervous control, it is possible to stimulate the muscles directly by external means. This is so-called independent effector action, the word "effector" here being used to describe motor organs of which muscles are typical. An example of such direct muscle stimulation is the response of a fetal arm or leg brought about by the direct electrical stimulation of the member. The first activity of the organism's own neuromuscular mechanism almost certainly does not occur until approximately six weeks after fertilization. Probably not until the age of eight weeks does response to external stimulation which involves sense organs and the central and peripheral nervous system become possible. This first effective stimulation results from the activating of the sensory endings of the skin.

In general it is safe to say, therefore, that at about the second month after fertilization the developing human organism first begins to be capable of responding to changes in the environment in which it is growing. In a fetus estimated at between eight and nine weeks of age strong "protective movements," as they may be called, have been noted. Such movements of both legs and the opening of the mouth have been observed following strong stimulation.

Fetuses at this initial period of response to external stimulation show slow asymmetrical and relatively noncoordinated movements.

Much has been written upon the question as to whether or not the first reactions of the growing human fetus are precise and reflex-like or whether they should be described as involving the generalized mass-action of many muscles. In the study of a good many different forms of infrahuman mammalian fetuses, as well as the observations made upon operatively removed human fetuses where pregnancy was interrupted in order to protect the life of the mother, it is clear that either description may sometimes be given with some apparent observational justification. In the young guinea pig fetus, for example, the first response to external stimulation is almost certainly a slight bending of the head and a correlated slight twitch of one forelimb. This fact has been established by the present writer and his associates after the study of many different fetal litters at just this zero point in the behavioral sequence. Certainly this response may be described as reflex activity. On the other hand, it is not possible to assert that this movement is unrelated to the general bodily posture of the entire organism. Thus those who like to say that all specific behavior is generalized from previously more diffuse behavior may be able to interpret these observations to fit that formula.

In this connection it has become recognized that the study of the growth of effective and adaptive action in certain of the lower vertebrates such as the free-swimming salamander *Amblystoma* has much to contribute to a general understanding of the first stages of growth in the human individual. The late George E. Coghill made detailed studies of the development of behavior in this type in relation to the growth of its nervous system. These studies have probably never been matched in completeness or in the clarity with which they have been interpreted. Coghill's analysis of the onset and development of the swimming reaction of the salamander, for example, involves a consideration of the following five stages: (1) a normally nonmotile state in which, however, direct muscle stimulation is possible; there seems to be good evidence that this stage is paralleled in the human fetus as noted above; (2) what may be called an early C-flexion stage, in which a light touch on the skin of any portion of the

body leads to a bending of the entire body to form a C or a reversed C; (3) a tight-coil stage in which this C reaction to either the right or left becomes more pronounced; (4) the so-called S reaction, which is characterized by a reversal of flexure before the previous flexure has been completed by the tail end of the organism thus transforming the C or reversed C reaction into an S or reversed S reaction; this S stage can thus be seen as leading to a sinuous slow swimming behavior of the total organism; (5) the speeding up of the S reaction so as to produce the typical rapid and effective swimming movement of the amphibian larva by means of which it darts through the water. Coghill has described the neural development which parallels this growth of behavior.

In the human fetus at the time the first response to external stimulation begins, the limbs have already developed. This is not true in the salamander, which swims with its body before it has functional limbs. Nevertheless there is probably more than a mere analogy between the rhythmic pattern of behavior involving the forelimbs and hindlimbs, that is, the arms and legs of the human fetus, and the primitive S reaction of the salamander.

Davenport Hooker, one of the ablest students of the development of the human fetus, says that in a fetus nine and a half weeks of age the portion of the skin which has become sensitive enough to elicit reflexes is restricted to the region about the nose and mouth. The responses that can be called out by stimulation of this area at this age include rotation of the rump and flexion of the body, as well as movement of the neck.

It is at about this period, between nine and twelve weeks, that so-called spontaneous behavior of the human fetus is first noted. This is an especially important observation. Anyone who is interested in the later activity of the living human individual must necessarily be concerned with this first beginning of activity which seems to well up from within the organism. Such behavior seems at first sight to be qualitatively different from behavior resulting from external stimulation. It is indeed this capacity for apparently spontaneous activity which has led in the adult human being to almost all of those characteristics which we think of as basic to the freedom of man. Some writers have even spoken of such behavior as not *caused* but

as a *cause*. The first spontaneous activity of the fetus, however, must not be considered as uncaused. Certainly we have no reason to think that it results from some new nonbiological force related to what nonscientific writers call "will power." Rather, such reaction may be seen as a natural working out of the growth process of the organ systems of the fetus itself. H. C. Tracy, in a careful study of the development of behavior in fish soon after hatching from their eggs, points out that these little larvae normally lie quiescent at the bottom of a containing vessel. Then suddenly they move. On the basis of a study of this spontaneous behavior this investigator comes to the conclusion that the onset of these reactions follows the cumulative development in the blood stream of the organism of what are called metabolites or the products of the life processes of the cells of the organism. As these products of cell activity build up, the oxygen available to the tissues gradually decreases. This leads to a slow and complex change in the chemistry of the blood. According to Tracy this change is cumulative, and when the metabolites build up to a special point, sensitive centers of the central nervous system are stimulated and neural activity leading to behavior results. The result of this stimulation of the central system is a neural discharge to muscle groups which brings about a reaction of the body-moving muscles of the organism. Incidentally such responses change the relationship of the organism to its aquatic environment and again place it in contact with water in such a manner as to provide more oxygen. Tracy, on the basis of these studies, makes some suggestions which may apply at least by analogy to the early form of spontaneous behavior in the human organism. He holds that if external conditions could be kept constant, the activities of any organism would be determined by the cyclic changes in its own inner life processes, that is, of its own body metabolism. This would mean that the behavior of the total organism might well be rhythmic in its external environment as the beating of the primitive heart-cell system inside the organism is rhythmic in its organismal environment. This would mean that the total organism might be considered, as it were, to beat or react in a timed sequence to its external environment as a result of its own internal activity.

The observations just given point to an im-

portant fact. From the very early period in the growth of behavior the organism is activated not only from without but also from within. As a result of internally initiated movements the organism changes its orientation, and thus the pattern of external stimulation is changed for the organism even though there has been no stimulating alteration in the external energy field itself. Thus the external senses are newly stimulated, and continued adaptive behavior resulting from both internal and external stimulation goes on.

By the age of fourteen weeks the behavior of the growing fetus has become such that almost all of the body parts may participate in adaptive behavior acts. Sometimes response is so general that it seems to involve nearly all of the muscle groups in a sequence of responses. It is at this period for the first time that we find observers describing behavior as "graceful" and "delicate." In the period between thirteen and sixteen weeks of age the effectiveness of the responses of the growing fetus to accomplish "results" by reacting to its environment continues to develop. At this time every part of the skin can be stimulated in such a way as to release typical and often apparently adaptive reflex behavior. Neurologists who are interested in the control of behavior at various central nervous system levels are interested in such behavior. It is pointed out, for example, that stimulation of the sole of the foot can be shown at first to lead to independent action of the muscles under the skin that is stimulated. Next, true neural action comes to take over the control of these muscles. At first the connection is in the spinal cord. Still later, subtle changes can be noted in the reactions of the toe and foot as progressively the centers of the brain located in the medulla, the thalamus, and finally the cortex are involved in mediating such responses.

From seventeen weeks to normal birth time almost all of the reactions which are noted in the human baby in the first days after birth gradually appear. In the latter part of this period operatively removed *premature* fetuses show many responses which are characteristic of the newborn child.

One of the best avenues for the study of the characteristics of human behavior previous to birth is the study of the sensory capacity of the fetus. As noted above, the first sensory field to become effective is that of the skin. The skin

is made up of a mosaic of sense organs or receptors which include those specified for mediating stimulation by soft and deep pressure, temperature and pain, and, it may be, other modalities. It is interesting to note that the fetus in acquiring cutaneous sensitivity develops before birth the ability to localize the point stimulated by moving a limb to the point touched.

The author of the present article was at one time so convinced of the truth of what has been called the learned character of an organism's ability to localize stimulation upon its bodily skin surface that he doubted facts to the contrary. When he read in the writings of Wilhelm Preyer, one of the earliest and greatest investigators of fetal life, that a guinea pig fetus before birth could localize with its paw the point touched, he felt that there must have been a mistake in the observation. Later, however, the writer's own experimental investigations confirmed in all respects this previous observation of Preyer, and showed that the idea of the learned character of such responses is almost certainly in error. The ability of an organism to localize the point stimulated develops as a result of the internal inherited or genetically determined growth of the nervous system. In certain instances it can be demonstrated that the localizing responses are made without any opportunity for previous exercise of the function. It is also interesting to note that weak or strong cutaneous stimuli have quite different effects when applied to the skin surface of developing fetal organisms. In general a weak stimulus elicits much less general activity than does a strong stimulus. In a good many instances a weak stimulus applied, for example, to the pads of the paws of a mammalian fetus may lead the fetus to move *toward* the stimulus. It reacts to such soft stimulation as if to secure more of it. A strong pressure stimulus, on the contrary, when applied at the same point may cause the organism to withdraw the member touched and then, by the use of more general muscle groups, the whole organism sometimes moves away from the point stimulated. Experiments conducted by the writer have shown the effect of strong and weak cutaneous pressure stimulation in quantified terms. Similarly it has been demonstrated that cutaneous temperature receptors may be stimulated by stimuli cooler or warmer than the physiological zero of the organism. In general the further

from this physiological zero, that is, the "stronger" the temperature, the more apt such stimuli are to call out responses.

A good many very specific cutaneous reflexes may be observed in fetal mammals and in the human fetus. The writer's own work on the development of so-called *reflexogenous zones* in the fetal guinea pig has convinced him that in a quiescent fetus in a normal posture there is typically one behavior act or reflex and only one such act that is set off by the optimal stimulation of each cutaneous area. These cutaneous "push buttons," as they may be called, are thus seen to be remarkably specific in their behavioral relation when the complexity of the central nervous system is considered.

The philosopher John Locke interestingly enough spoke of the pain sense of the fetus. Since the time of this early note there has been little direct experimentation upon the pain sense in mammals before birth. A number of casual observations show, however, that the application of stimuli must have caused gross destruction of the skin and subcutaneous protoplasm and not called out very pronounced movements on the part of the fetus. The present writer's experimental work tends to confirm the fact that an increase in pressure over that necessary to bring out typical responses to deep pressure receptors does not always seem, at least in infrahuman fetal mammals, to increase the extent or intensity of response. In many instances the light pressure of a fine hair may lead to extension, and stronger pressure, as noted above, to retraction. But very strong, "painful," or even obviously destructive stimulation, applied to the same point by needle or heated wire, may not make any observable difference in the elicited response over that noted to strong pressure stimulation. It has been suggested that the necessary pressures and strains of mammalian birth would cause a very severe shock to the central nervous system if the pain mechanism were highly developed during the period before birth.

There can be no doubt that the proprioceptive senses, including neuromuscular spindles, are found in a well-developed form as early as the fourth month of fetal life in the human individual. No one who has observed mammalian or human fetal behavior can doubt that, in the later period at any rate, many of the responses noted are reactions following muscle receptor

stimulation which has itself been initiated as a result of previous activity. Extremely well correlated and apparently purposeful movement can be observed in late fetal life which almost certainly involves stimulation which originates in the stimulation of receptors in the muscles and in other related proprioceptive receptors.

Many students of behavior agree that *locomotion*, as seen, for example, in the crawling movements of the fetal opossum, *sucking* in order to bring in nutriment, and *air breathing* are three of the earliest essential behavior systems of the newborn mammal. It is interesting to note that each of these responses in its developed form depends to a certain extent upon proprioceptive stimulation.

The so-called static receptors in the nonauditory labyrinth of the internal ear are probably to some extent functional before birth. It is, however, very difficult to isolate behavior released by these static receptors as contrasted with behavior released by the stimulation of muscle and other so-called proprioceptive sensory systems. Those who have studied the early responses of fetal mammals have been able to elicit some of the very special patterns of limb extension as a result of turning the animal's neck to the right or to the left. Minkowski, one of the most thorough students of human fetal behavior, believes that most of the fetal responses related to the nonauditory labyrinth may be thought of as the result of effective stimulation of receptors in the semicircular canals. It is well known that stimulation of the nonauditory labyrinth by rotation and in other ways brings about compensatory movement of the muscular system of the organism and especially directs the movements of the eyes. Zing Yang Kuo, a distinguished Chinese student of early fetal behavior, has demonstrated the fact very clearly that the nonauditory labyrinthine control of eye movements is, at least in certain infrahuman animals, developed long before the control of eye movements may be brought about by retinal stimulation with light.

Historically, there has been some discussion of the organic senses as they begin to be functional in the fetus. The philosopher Locke, who has already been quoted as making an observation on the pain-sense in the fetus, holds that in the early period of fetal life the unborn child has perhaps, as he puts it, "some faint ideas of

hunger and thirst." Certainly at the present time very little can be said that is definite concerning the part played in fetal behavior by stimulation which may originate in the organic senses, or, as they have been called, the interoceptors, which are related to the internal digestive and other organ systems of the body. At a previous point in this discussion some reference has been made to a theory of *drives* or *motivations* which holds that the activity of the organism may be conditioned in part by alterations in the internal environment of the individual. It should be noted however that, at least in certain instances, another form of internal stimulation besides that already discussed, namely, stimulation resulting from the activation of receptor organs inside the organism and related to hunger, thirst, satiation, and the like, may be considered. It seems altogether likely, for example, that in a state of hunger the internal stimulation which is affecting the organism may at times be related both to the chemical change in the blood acting directly upon certain centers in the nervous system and also upon stimulation of receptors internal to the organism resulting from alterations in the rhythmic hunger contractions of the stomach which appear sometimes when no food is present in the stomach.

There has been a good deal of discussion in the earlier literature of fetal sensory processes as to whether or not the unborn organism could taste the liquid of the environment in which it existed. The study of the nature of receptor stimulation leads us to believe that all stimulation depends upon environmental change and upon change which occurs rapidly enough to bring about a shift in the receptor mechanism such that a wave of negative depolarization (i.e., stimulation) may be initiated in the receptor cells and associated neural mechanism. Certainly there seems to be very little evidence that any such rapid or violent change in the characteristics of the amniotic fluid can occur during fetal life so that the taste buds would be stimulated. What has been said about taste also applies to olfaction. The olfactory receptors could be stimulated by liquids even if not by prenatal airborne stimuli provided rapid enough changes in the amniotic fluid might be detected. Since no such changes have been observed, there is little reason to suppose that smell is an effective sense before birth. In all work upon smell in

newborn animals great care must be taken to isolate the stimuli used so that they will not affect what neurologists call the "trigeminal components" or the receptors related to the "common chemical sense" as described by G. H. Parker. If ammonia, for example, is used as a smell stimulus, there is very little doubt that instead of stimulating the olfactory receptors exclusively, the pain receptors of the common chemical sense will almost certainly also be brought into action. Experiments are reported on newborn infants, or at least on 18-day old infants, in which a breast nipple on which kerosene had been placed was refused, while the other nipple, which had been treated with an odorless oil, was eagerly taken.

Kussmaul, one of the well-known students of early sensory processes, has stated that "the sense of hearing sleeps more deeply than any other sense." More recent experiments in which the present writer has participated seem to indicate that as a result of the use of electrical methods of investigation the truth of this observation may be qualified. The receptor mechanism for auditory stimuli is effective before birth, and as soon as the liquid filling the ears is removed, the late fetus can hear. This judgment is made on the basis of evidence that is both electrical and behavioral. In this connection there have been a number of interesting observations and experimental studies of the responses made by normal human fetuses to loud auditory stimuli sounded outside the abdominal wall of the mother.

From the general psychological point of view there can be no doubt that vision is the most important human sense. It is certain that in normal prenatal life there is little likelihood that any effective light stimulation acts upon the retina of the fetus. There is evidence, however, that pronounced differences between light and dark bring about specific reactions in infants born as much as two months before the normal term. At the time of normal birth the optic nerve and related structures have not yet fully developed anatomically. This suggests that the visual mechanism can function long before it is anatomically fully developed. One of the early responses to develop to strong light stimulation is the contraction of the pupil. There is a great difference in the relative level of development at the time of birth of the eyes of different mammals. The guinea pig, for example, is born

with eyes open and apparently in an almost adult state. In the cat the eyes are closed far from functionally effective at birth.

In the long summary of the development of the senses that has just been presented, the nature of the stimulus control of behavior in the prenatal period has been explained. Something of the character of what has been called sensory experience in the unborn infant has also been suggested. Speculation on early introspectively known sensory experience is probably rather profitless. There does seem to be some evidence which suggests that growth during active fetal life and infancy is paralleled by a development of sensory experience in which more and more specific sensory patterns come to be differentiated out of a general matrix. Indirect evidence favors this view rather than the older notion that sensory experience at any given moment is a summation of previously more simple and "pure" experiences. As Coghill has well pointed out, both the development of behavior and the hypothetical development of sensory experience seem to follow an old evolutionary rule. Growth in most cases involves the gradual development of the specific and the particular from previously more general and homogeneous antecedents.

As has been suggested previously, it is dangerous to take such a simple formula as a complete statement of the way in which fetal behavior or experience does develop. It has been noted above that the cutaneous receptors of the organism may at very early stages be thought of as push-buttons which initiate specific patterns of response or reflexes. In certain instances it is possible to show that these very specific responses begin as soon as any response can be elicited by stimulating the particular receptor area or reflexogenous zone in question.

In fact it is too much to hope that a general and simple formula concerning fetal development can be provided. It seems, as is so often the case in science, that the careful student of the development of fetal behavior must turn back time and time again to direct observation and to the study of growth of functions of specific receptor and motor systems in order to explain how behavior develops. It is clear that an increasingly exact knowledge of the myelination time of various levels of the peripheral and central nervous system and of the growth of specific neural pathways and connect-

ing mechanisms will add greatly to the understanding of the time of the onset of specific responses in the organism. As pointed out above, Coghill has carried out work of this sort in a way that will always remain a model for students in his study of the correlation of behavior and neural structure in the developing salamander. Windle and his associates have made many similar studies of birds and mammals. Davenport Hooker and his coworkers have similarly made a most propitious beginning in the analysis of the neural basis of certain specific forms of human fetal behavior. In spite of studies of this sort the scientific literature still contains some dogmatic and only partially demonstrated statements concerning the anatomical basis of, for example, the first movement made by fetal mammals. There are theories of the maturation of the nervous system which involve the reorganization of neural elements at synaptic junctions; there are theories which assert that first responses depend upon myelination of the nervous system; and there are chemical and physical theories which have been developed to account for the functional growth of the nervous system in relation to behavior. It seems increasingly clear, however, that the final answer in regard to the basis of any behavioral act will almost always have to wait for most careful, detailed, and specific functional and morphological analysis.

A good many questions of a more general psychological sort are at times asked about the mental life of the fetus. For example, the question occurs in the literature: Does the unborn child have intelligence? It is clear that the answer given to this question will depend upon the way in which one defines intelligence. If intelligence is defined as "dependent upon past learning of the organism," it may with some assurance be said that the fetus probably does not show intelligence. If on the other hand intelligence is defined so as to include adaptive responses which may result from inborn reflex or other neural mechanisms, then obviously the fetus does show intelligence.

In the last few sentences the problem of learning in the fetus has been referred to. There has been a good deal of discussion concerning the possibility of learning before birth. Certain recent experiments have been carried out on pregnant women in an effort to show that conditioning may be brought about in the fetus

before birth. As yet this field has not sufficiently advanced to allow sure conclusions to be drawn. In general it may be said that before birth the behavior shown by the organism is a function of the inherited make-up of that organism as brought out by the internal and external environment then acting upon the fetus. In making this statement the writer is not unaware that without a constant environment the mechanisms of heredity could not have made possible the development of the nervous system or the functional behavior systems of the fetus. Experimental study seems to indicate that not until after birth and then only very slowly is it possible to bring about conditioned responses or other learned reactions in the newborn organism. The fact that the fetal animal cannot be "conditioned" requires the psychologist who is interested in the mental life of the fetus to deal almost exclusively with inborn reflexes as a measure of the sensory or other processes which he is investigating.

From the standpoint of educational psychology, therefore, it can be said that all the psychological reactions described in this chapter have been concerned with the development of the sensory neuro-muscular mechanisms which are antecedent to those reactions which result from learning. It should be remembered, however, that learning involves the modification of already functionally effective behavior, and that such modification can take place only in a brain which has developed to the stage in which neural learning is possible. The matrix of behavior with which the educational psychologist begins when he first speaks about learning or any type of environmentally determined modification of response is the inborn behavior capacities of that very wonderful creature, the human fetus.

It has long been recognized that to begin the study of anatomy without an understanding of embryology, that is, to attempt to describe the adult form of living organ systems without understanding how these structures developed, would be unthinkable. It may be a slight exaggeration to suggest that a similar relationship exists in psychology, but the present writer hopes that the discussion presented above will show the reader that fetal life is important in any complete understanding of mental life. The reactions of the living organism before birth are significant for one who wishes to understand

as completely as possible the real basis of the adult mind of man.

LEONARD CARMICHAEL,
Tufts College

FRAMES OF REFERENCE IN PSYCHOLOGY.—A frame of reference is either a limited universe of discourse or a world view which takes a limited universe of discourse for its starting point, and represents an extension of that limited universe. The statement of a psychological world view is a metapsychology, and only a minority of psychologists have formulated frames of reference in that sense of the term. That minority includes, however, great names like that of William James and Sigmund Freud. On the other hand all psychologists have a frame of reference in the narrower sense of the term. All scientific research presupposes some limited universe of discourse. In other words all research is based upon the assumption that some things are highly relevant to the solution of a particular type of problem, while other things are less relevant and still others may be totally irrelevant. Any frame of reference in psychology is based on beliefs concerning what data are relevant to psychology, concerning what observational methods are useful, and concerning what scientific constructs are permissible.

Contemporary psychologists agree almost unanimously that the aim of psychological science is to increase man's ability to understand, predict, and direct the behavior of living organisms. There is considerable controversy, though, about how broadly the term "behavior" should be defined. Psychology uses, in the quest to fulfill its aim, three most general types of data. All psychological frames of reference admit the importance of data pertaining directly to the organisms which are being studied. All accept the value of collecting data about the stimulus environments of those organisms. Some psychological frames of reference admit the relevance of data which pertain to the objective products of behavior by the organisms. Only today is a start being made toward adequate exploitation of that third type of data. The use of cultural artifacts of many kinds as data for interpreting behavior promises to have results which will greatly reorient prevailing frames of reference.

Experimental behaviorists observe interactions between organism and environment with the purpose of isolating stimuli which can be char-

acterized in terms of strictly physical measurements. Such psychologists use the following classes of stimuli as data for explaining behavior: mechanical stimuli, electrical stimuli, chemical stimuli and photic stimuli. On the other hand the frame of reference which is commonly accepted in social psychology and clinical psychology does not stress the physical aspects of environmental data. To a social or clinical psychologist the fact that a neurotic child's father is a "snobbish" person might be acceptable as a basic datum for interpreting the child's behavior. Some psychologists concentrate upon those data which are described in a physicalistic language in terms of such variables as length, breadth, thickness, duration, energy, etc. Other psychologists concentrate rather upon environmental data which must be characterized in sociological language in terms of such variables as friendliness, defensiveness, aggressiveness, subjective time, etc. This difference in frames of reference arises from divergent purposes for engaging in psychological research. The clinician's aims, for example, are eminently practical while those of the student of rodent behavior are as completely divorced from the socially pragmatic as any aim could be.

Gestalt psychologists have made considerable use of physical stimuli as data in the study of perception. Members of the Gestalt school have stressed greatly the importance of achieving knowledge about the formal characteristics of groups of physical stimuli. The way particular stimuli are arranged in space and time is always an important datum within the Gestalt frame of reference. To a certain extent other contemporary psychologists, including even those behaviorists who impugn the value of studying experience as such, have accepted the general Gestalt principle. Many experiments have tended to prove that differences in formal relationships among stimuli are decisive factors in the causation of response differentials.

Certain parapsychologists assert that there are purely mental (non-physical) stimuli. Other parapsychologists believe that hypothecated acts of extra-sensory perception must be stimulated physically. Some believe that one brain may affect another through radiations or waves, having as yet undetermined physical properties. Since it is very doubtful that extra-sensory stimuli, whether mental or physical, have been scientifically observed, they probably should not

be said to constitute one class of psychological data. Rather, they are constructs which are hypothecated to explain certain avowedly extra-chance results in experiments in which subjects are asked correctly to name certain stimulus-objects which they supposedly cannot perceive by sensory means. In later paragraphs the topic of psychological constructs will be discussed on its own merits.

Next the bearing of different frames of reference upon the problem of data pertaining directly to organisms should be considered. Most psychologists use the following classes of such data: introspective data, behavioral data (changing relationships between the organism and its environment insofar as these are brought about by the organism's own movements), anatomical data and physiological data. Some include physiognomic data as a distinct type but this group might be classed under the anatomical category.

Extreme behaviorists have ruled out introspective data as a distinct type. It has been said that, since private experience is socially revealed through verbal behavior, the verbal behavior itself is the true terminus of observation. It should be noted in considering the merits of this contention that all observation of data involves mediating factors. When a camera is used in the study of behavior which is too rapid to be adequately observed by direct vision, for example, the observation of the behavior is mediated by mechanical factors whose possibly distorting influence must be duly considered. All measuring devices may have imperfections or might be mistakenly applied. And even perceptual agreement is relative to certain media of perception. Therefore the fact that introspective data are revealed indirectly is hardly unique in principle. Critical problems arise in connection with all observation. It should also be noted in evaluating frames of reference concerning introspective data that verbal expressions may have either an objective reference or a subjective reference. Eidetic imagery has been verbally described and, in some cases, eidetic memory has been found to be much more accurate than other kinds in certain quantifiable respects. For example, Gordon W. Allport found in his study of eidetic memory that British school children, after having seen a picture for half a minute, could turn away from it and project their images of the picture on a screen. Some could spell, forwards or backwards, the German word

"Gartenwirtschaft" which had appeared over the door of a building in the picture. This reading backwards was more rapid and accurate than any reverse repetition of similar letter combinations observed for half a minute and recited on a non-eidetic basis. This illustrates the fact that the subjective sphere is operationally meaningful. It is no more and no less meaningful than the physical sphere. Data of all types become socially significant through symbols but the behaviorists do not assert that symbols are the only legitimate data for psychology. Whether a fact is subjective or physical, it becomes scientific evidence only when it is described in a protocol statement wherein an observer reports his experience of it.

Some psychological frames of reference require the use of data which reveal the objective products of behavior. Psychological anthropologists use cultural artifacts as data. Personal document analysis investigates personality on this basis. The psychology of art is so based. Some animal psychologists study the nests which birds have constructed, the dens which animals have dug, the weaving of webs by spiders, and other productive data. The quantity of defecation and urination is sometimes used as an index of emotionality in the rat. To illustrate further, if two men engage in physical combat and one man is wounded, the kind of wound, its extent and its bodily location are data which reveal something about the personality of the man who inflicted the wound. Handwriting is a productive datum. Machines are data. The relative neglect of this manifold realm of observable facts related to behavior is methodologically most unfortunate, and is now being corrected by forward looking psychologists. Approaches to a science of behavior which are based on much observation of stimuli and little observation of products are approaches which bypass those characteristics of adaptive behavior which differentiate it from inanimate processes. Psychologists who stress stimuli and neglect products regress toward a frame of reference which is proper rather to mechanics than to the science of behavior. Most important of all for the scientific understanding of human behavior is the use of those products which represent and express man's attempts to interpret the world and his place in it. The products of artistic and reflective activity, products such as formal esthetic objects and informal personal documents, may be the

most valuable data without exception for the quest to understand man.

Any psychological frame of reference must legislate concerning what observational methods are legitimate. A permissible approach to this branch of the topic is to consider some conflicting frames of reference in animal psychology. The study of animal behavior is based on two chief observational methods. Systematic naturalists observe animal behavior in the natural habitat and try to discover norms for various species. Experimental psychologists study animals in laboratory situations. It has been said that field observations are of little scientific value because in the field there are so many variable factors which cannot be controlled and whose influence cannot be appraised. The naturalists have a rejoinder, however. They state that most laboratory experiments include so few variables and so rigidly restrict the animal's operations that the resulting behavior must be regarded as being rather a product of human ingenuity than of any general trends in animal behavior.

Possibly some animal experimentation is open to those charges, and many experimental psychologists would admit that field observations and laboratory work are complementary rather than mutually exclusive methods. The allegation that the higher, more complex animal activities can be studied only in the natural habitat, however, clearly is refuted by the implications of certain types of experimental work. In illustration may be mentioned John B. Wolfe's pioneering investigation of the effectiveness of token-rewards for chimpanzees. Working at the Yale Laboratories of Primate Biology, Wolfe reached some definite conclusions about the most complex, symbolic behavior which has ever been observed in infra-human organisms. In this experiment chimpanzees were trained to use variously colored tokens as means to satisfaction of various drives. The animals learned to insert the tokens in vending machines in order to get food. The effectiveness of tokens as stimuli to work (involving manipulation of weight-lifting levers) was investigated. Their effectiveness in eliciting competitive behavior in social situations was noted. The animals learned to show preference for tokens of a certain color after that class of tokens had been associated with additional rewards. Wolfe's work, the nature of which can only be suggested here, illustrates that an experimentalist's frame of refer-

ence by no means dictates that he must concentrate upon the simpler animal behavior. It is unfortunate that very few animal experimentalists have a special interest in primate behavior of complex types because animal psychology as developed to date has few points of contact with human psychology. In other words, John B. Wolfe's work is rather exceptional in that it does have a definite bearing upon the understanding of human behavior while the major part of animal psychology has implications which refer to human action so indirectly and remotely that the pragmatic value is difficult to define. For example, it is doubtful whether experiments concerning learning even by so relatively high an organism as the rat have the least value for the quest to make human education more efficient, economical and enjoyable, while it is certain that they do not have an extraordinary value in these respects. Even in regard to symbolic behavior in primates, Wolfe did not suggest that symbols were responded to as a unique class of things. Those who suppose that the rat or even lower forms like the chicken show this characteristic human trait, perhaps one of the most crucial factors in human problem solving behavior, would not be taken seriously by those who have observed the appalling differences between man and even the highest primate animals.

Frames of reference for the study of human behavior differ most profoundly concerning the scientific status of case study methods. Some psychologists say that work upon the single case may be an admirable artistic activity but that it is definitely not a scientific activity. This view is based on a certain interpretation of the fact that scientific laws, properly so-called, concern relationships between whole classes of facts. The cognitive ascent from the datum to the law is a rise from particularity to generality. The practical implications of this truth, though, require very cautious definition. The different situations in a single life history do constitute a class. This class is in turn composed of definite sub-classes which may be differentiated in terms of the various types of striving or, if convenient, in any one of many other ways. Thus there is plenty of room for generalization about trends within a life history. A life history includes different kinds of striving, a quest to unify ideals, a progressively differentiated interpretation of the world.

Statistical studies of the behavior of many individuals have some use for predicting the behavior of a given individual. However, principles of probability have been used most uncritically by some persons. Gordon W. Allport somewhere explains this. He notes that if we know that seven out of ten Americans go to the movies each week, it by no means follows, as some would suppose, that the American Mr. Smith has seven chances out of ten of going to the movies this week. Mr. Smith is a particular individual, truly an American, but equally truly a member of many other classes of individuals. For example, he may be a member of the Catholic Church or the Communist party. He may be one of those who is about to die of cancer. He may be one of those who dislikes the policies of the Hollywood movie magnates. He may be a Shakespeare enthusiast. Similarly, this week belongs to other classes than the class of weeks in American history. It is also a week in world history and it may be one of those weeks in which Mr. Smith's residence is affected by a flood. Depending upon his specific attitudes, many of which may be fairly permanent personal traits, and also depending upon what movies are available, it may be that Mr. Smith is ninety percent likely to attend a movie this week, or ninety percent certain not to attend. In order to learn whether a high degree of certainty exists, a case study method would have to be applied. This method would cover not only many of the relevant classes of events mentioned above, but would also involve weighting the relative importance of each class. In some cases achieving even a roughly accurate weighting of factors would be more important than achieving more than a rough estimate of the probabilities related to the individual factors.

Gordon W. Allport has also noted that one large section of the psychological profession, namely, the clinicians, claims large success in predicting behavior on the basis of evaluating single cases in multi-dimensional terms. That the chief aim of science is to realize the greatest possible accuracy of predictions in specific situations and concerning particular events may not be generally accepted by psychologists, but contemporary philosophers of science do stress that proposition. An individual's behavior could be predicted with the highest accuracy only by considering all the classes to which he belongs,

and the relationships between influences exerted by each. Psychologists of personality, like Allport and, in a past epoch, William Stern, have stressed the fact that some logically definable classes have only one member, and probably the relevance of these could be appraised, if at all, only by intuitive methods based on extensive clinical experience. Allport has argued that in order to understand a personality the psychologist's own personality must be at least as complex as the subject's. This would seem to be a necessary condition of clinical insight but not a sufficient condition.

Psychological frames of reference differ not only in regard to what data are admitted, and in regard to observational methods, but they also differ concerning what constructs are recommended as being the best devices for interpreting data. Some psychologists use mentalistic constructs, some use physicalistic constructs, and some use neutral constructs. William McDougall and his successor Helge Lundholm use mentalistic constructs as, to a certain extent, do the depth psychologists like Jung and Freud. Most so-called objectivists use physicalistic constructs. Kurt Lewin, a Gestalt psychologist, uses neutral constructs, and perhaps the constructs used by personalistically inclined psychologists, like G. W. Allport, should also be characterized in this context as being neutral. William Stern, a personalist of last generation, stated that such personal functions as language and symbolic behavior, generally, are psychophysically neutral. Allport defines attitudes as psychophysical states of readiness to respond in specific ways.

A construct is an hypothetical structure the nature of which is suggested to the scientist by the facts and relationships which he has observed. The construct must be compatible with the empirical evidence but goes beyond the empirical evidence. A person as constructively interpreted is a system of characterizable potentialities which are compatible with his observed past behavior, and in terms of which his behavior in conceivable future situations may be predicted. A constructive hypothesis is tested by further observations and especially by those rigorously controlled observational situations which are called experimental. The more often predictions on the basis of constructs are confirmed by observations, the more nearly the constructs are assumed to be descriptively adequate to reality. By descriptive adequacy is not

necessarily meant revelation of ultimate, meta-psychological reality. The neutralist believes that the workings of the substratum of behavior may be predicted in constructive terms even if those terms do not describe what a direct experience of the substratum would be like. The constructive neutralist predicts certain future manifestations of the substratum, aspects of its behavior in conceivable situations, but does not pretend to know the substratum as a "thing in itself" or to know it in a cosmic or absolute perspective. The physicalist and the mentalist both more nearly assert that they know ultimate reality than does the neutralist. Personalistic neutralists like Gordon W. Allport tend more nearly to identify their constructs with ultimate reality than do impersonalistic neutralists like Kurt Lewin. Those of personalistic tendencies strongly repudiate the ultimate beliefs of physicalists, and partly repudiate mentalistic contentions. Neutralists of impersonalistic tendencies are philosophical sceptics.

The chief justification for using mentalistic constructs is that some behavior, although not directed by conscious intentions, is as complex and seemingly as purposive as is consciously directed behavior. Automatic writing, behavior obedient to post-hypnotic suggestions, some symptoms of conversion hysteria and many other types of involuntary behavior, seem to be meaningful, adaptive and in some cases seem to presuppose something like reasoning. Phenomena of co-consciousness support this viewpoint, strongly. It has been argued that categories which are derived in the first place from the phenomenology of conscious endeavor logically must be projected upon some, or all organic activities which are not accompanied by intentional deliberation.

The chief justification for using physicalistic constructs is that some of them can be converted directly into data. Thus the dichotomy between datum and construct is bridged in part. For example, if a person deteriorates greatly in intelligence, the interpretation might be that some cerebral pathology accounts for the changes in observable adaptive behavior. Such pathology might then be observed indirectly by means of the electro-encephalogram, or directly by means of skull operations. Mind is not observable by means of the sense organs but body is observable by sensory means. Mentalistic constructs are never objectively observed but some things

which once had the status of physical constructs later have the status of being sensory data. The mentalist, of course, regards the physical constructs which are empirically validated as being simply additional manifestations of mind. He argues that organic structure, like behavior itself, may express purpose, however imperfectly. It is further argued that, while material arrangements are conceivable expressions to the finite mind of spiritual purposes, the existence of consciousness in what originally was a material world, and what is a world in which all causes are physical, would be logically ridiculous. Confronted by the physicalistic critique, the mentalist is forced to make metapsychological statements. Mentalists developed metapsychology, though, even before they were so irritated.

The chief justification for using neutral constructs is that through their use the psychologist may theorize beyond the limits set by the momentary development of anatomy and physiology without resorting to metapsychological speculation. Neutralists point out especially that neurophysiology is in a very primitive stage of development. They point out that adequate comprehension of the physical substratum even of the simplest act of learning does not exist. They point out that the physiological substratum of cultural motives is to date an entirely speculative matter. Neutralists claim that physicalists evade the task of scientific psychology by resting content with the hope that advances in anatomy and physiology some day may make an adequate interpretation of behavior possible, while actually an adequate interpretation might be approached even now were specifically psychological constructs used to correlate available data. Kurt Lewin finds in the concept of neutral tension systems which may be related in dimensional but non-physicalistic terms a device for correlating behavioral data. Gordon W. Allport applies the concept of adaptive and expressive psychophysical traits, including the object-directed attitudes. Just as biologists assume that the facts of heredity may be correlated by means of the theory of genes, and physicists make use of such concepts as those of electrons, protons, neutrons, positrons, etc., so neutralistic psychologists attempt to find theoretical constructs which are sufficiently complex in their conceivable relationships to serve the purpose of interpreting behavior and of providing a rationale of prediction, even although the con-

structs cannot be directly observed and need not be equated with ultimate reality.

Many psychologists whose writings betray decidedly physicalistic biases are totally unaware that certain propositions which they accept on faith are highly controversial. One leading American physicalist and behaviorist, though, is strongly interested in methodology, and has published several discussions which evince some sophistication. He is Clark Hull, the Yale experimentalist whose views, while being definitely behavioristic, have caused some consternation among his more dogmatic colleagues. Hull has devised such complex constructs as the "habit family hierarchy." These are designed to refute the criticisms of behaviorism which have been launched by those psychologists who believe that only teleological or quasi-teleological categories can account for the adaptive flexibility of individual behavior. A habit family hierarchy, as defined by Hull, is a system of related locomotor habits all of which can be activated by the same initial situation, and all of which, once aroused, direct the organism toward the same terminal situation. Each habit in the system differs from all others in regard to the route of locomotion which it causes the animal to follow in passing from the initial to the terminal situation. The system is a hierarchy because one of the habits is most readily aroused, a second is aroused if the locomotion based on the first is blocked, the third is aroused when the second is blocked, and so forth. Hull supposes that to learn one habit through practice is in some cases equivalent to practicing a whole system of related habits. Such ready acquisition of alternative route-habits he supposes may depend upon more generalized learning in the past such as past implicit realization that while the shortest distance between two points is a straight line, there are more circuitous lines which connect the two points, and that the less any one deviates from the most direct, the shorter it must be.

The concept of habit family hierarchies fails to help us understand why various initial situations may have equivalent stimulus values, and why various terminal situations may have equivalent goal values. As G. W. Allport suggests in his book *Personality: A Psychological Interpretation*, the recognition of abstract similarities between situations and action guided by such recognition follows a phase of activity in which

the situation is interpreted. The organism adapts relevant habits in a unique way to the structure of what is for it a novel situation. The Soviet psychologist, S. Rubenstein, holds a similar view, and argues that the character of a habit, the degree of its flexibility and ease of transfer, must depend upon the degree of adequacy, differentiation, and generalization with which the conditions are known to which the formation of the habit is related. Thus flexibility of behavior is closely related on the one hand to general traits of intelligence, dependent upon inherited total structure as modified through behavior, and on the other hand is related to the learned comprehension of abstract principles of method for conducting operations of a specific type. Hull, Allport and Rubenstein all tend to dodge such concepts as that of insight, yet the adaptive behavior which they are concerned with constantly tempts the investigator to consider insight to be the basic factor. None of these investigators is prepared to accept a mentalistic frame of reference with its inevitable metapsychological implications. If they did so they would become philosophers, and they loyally strive to keep the psychological frame of reference bounded and closed rather than continuous with the whole of human reflective activity concerning that being which confronts us and in which we participate. Such exclusivistic tendencies are useful for maintaining a necessary division of labor. Philosophers, however, might well take the limits of psychological reasoning as one point of departure for the attempt to build a coherent human account of the fundamental structure of things in their totality. Only a small minority of contemporary psychologists feel that they are equipped to attempt any systematic philosophizing even if psychology be taken as the point of departure. A few, like Helge Lundholm, have made some attempts in that direction. Lundholm states that all psychological writing is metapsychological or philosophical if one frankly admits its most distant postulates or implications, and he is especially interested in defining those ultimates.

Psychologists of an earlier generation frequently were philosophers, also. William James, a founder of modern psychology, is remembered among the great philosophers. He combined certain beliefs about an hypothecated subliminal self with certain religious beliefs. He speculated that the subliminal self is a medium through

which man receives revelation from supra-human agencies. James did not accept the doctrine that there is a single mental continuum of which all minds are differentiations. He was a pluralist, and was what he himself called "a piecemeal supernaturalist." Helge Lundholm somewhere notes that a considerable number of artists, when conceiving their own state of mind as inspired, have meant that they were under the influence of supra-human powers or even of the divine power. Lundholm tends to affirm the belief that there is a general mental continuum, but he is sceptical about so-called inspired artistry. He thinks that a critical evaluation of evidence makes affirmation just as difficult as proved negation would be. Lundholm does not state that, were there a general mental continuum, certain mnemonic phenomena in it would correspond roughly to what the idea of personal immortality crudely implies. As R. F. Cregan noted in an article in *School and Society* titled "Man's Need for Immortality, and Modern Thought," survival may be conceived not in terms of the nature of the individual at a final moment, but rather in terms of a synopsis of many moments in a life history. Such a belief would presuppose the attribution of mnemonic traits to that medium within which finite existences emerge and function. Immortalization might be conceived of as relative and selective. Not every pattern of events need be retained, and retention and further development of patterns might be for short periods of time, for longer periods or for all time, depending upon the circumstances. Few psychologists are interested in metapsychological speculation of these types even although such speculation does provide a rationale for certain pragmatically necessary beliefs.

Sigmund Freud, the founder of psychoanalysis which in general has a mentalistic frame of reference, also formulated a metapsychology in his monograph titled *Beyond the Pleasure Principle*. This metapsychology is a curious blend of teleology and a kind of materialism, and it is romantically pessimistic. The ultimate aim of all life, opines Freud, is dissolution or death. The living being is said to be a being under tension, and the drive to release tension is said to be a drive toward dissolution. Life has evolved, Freud thinks, only because external irritations have forced greater complexity upon it despite its will to death. Against Freud it

might be argued that, although increases in organic complexity may be caused by external irritations, this happens incidental to living plasma's equilibration tendency. Rather than dissolution, equilibration might be the inner trend, and this might become a trend toward greater complexity whenever disturbances produce a situation in which the only alternative would be either dissolution or more complex equilibrium. In a Freudian world devolution, regression and confusion rather than evolution, progress and learning would be the norms. Contemporary social processes and wars sometimes cause the thoughtful to wonder concerning which set of norms really prevails. Freud himself, a citizen of a nation which was defeated in the First World War, did not live in an optimistic social group, and at the time when he fled from Austria to escape the Nazis, the situation warranted optimism even less than before.

If Darwinian biology is neither optimistic nor pessimistic, Freud's biological philosophy is darkly pessimistic. Darwin stated that germ plasma achieves only chance variations. As a result, the offsprings of a given species in a given generation have different survival values which vary according to the laws of normal probability. In the struggle for survival the fit variants survive and so they reproduce their chance idiosyncrasies. Although Darwin would not agree with Freud that life seeks death, he nevertheless did not believe that it seeks to evolve into more complex forms. Still it may be asked whether random, non-purposive irritation of germ plasma would result inevitably in final variations which are also normally distributed. If there is an equilibration trend in living substance, then germ plasma might respond to chance irritations by becoming more complex in a greater number of cases than it would respond by becoming more simple. The effects of disturbances might be assimilated and balance be restored by the increase in complexity. As De Vries pointed out, the geological record indicates that for the most part evolution has been through a series of mutations. Seldom have mutations been in the direction of greater simplicity of structure. Often they have been toward greater complexity. Thus while Freudian biology is pessimistic, and Darwinian is indifferent, a truthful statement would probably be

positively optimistic, stressing progressive order rather than chance. Our whole scientific frame of reference stresses causality and organization. Within such a frame of reference notions like that of learning through the survival of random response differentials, evolution through the survival of random inheritance differentials, and economic improvement through the survival of random differentials in the efficiency of industrial production represent an unfortunate and fantastic defeatism.

One of the most comprehensive world views taking its point of departure from an essentially psychological frame of reference was that formulated by the great German philosopher Friedrich Wilhelm Nietzsche. The depth psychologists have learned much from his thought, and could learn more. Nietzsche's writings sometimes had an erratic form and sometimes involved obscure symbolism. Therefore few psychologists have understood his reasoning. Its systematic structure and its bases in psychology which he called "Queen of the Sciences" are elucidated by George Allen Morgan, Jr., in his comprehensive book titled *What Nietzsche Means*. Nietzsche interpreted conscious mind as a manifestation of unconscious impulse, and the world as an expression of cooperating and conflicting wills to power. Science, he argued, should interpret all things in the perspective of their growth in power, and all organizations as more or less economical compromises among different power centers. His criticisms of the physicalistic frame of reference are among the most subtle, yet definitive statements of the teleological type of psychological and philosophical thinking.

Georg Groddeck, a German psychoanalyst, has developed a metapsychology which interprets all physiological states in teleological terms, and which hints at an idealistic world view. His *Book of It* is a masterpiece of humorous writing, treating some serious theoretical issues with a nicely calculated flippancy and a bizarre extravagance. Carl Jung, the Swiss Analytical Psychologist, has also developed a metapsychology which tends to define all finite systems of motivation as differentiations within a universal libido or life force. William Stern, the founder of critical personalism, defends the thesis that the most all-embracing reality shares certain traits with finite persons. Like the psy-

chophysicist Fechner, Stern attributes personhood somewhat hastily to some natural systems, for example, the solar system, which do not obviously reveal any adaptive behavior.

Social psychology is still in a very chaotic state, methodologically. No one frame of reference is widely accepted by social psychologists. The attempt to interpret behavior with reference to individual variables and social variables, somehow assimilated into a single universe of discourse, presents extreme difficulties of logic and research technique. George Herbert Mead, of the University of Chicago, has made important contributions in this direction. Personality is formed by a process of integrating various rôles in social situations, Mead supposed. Those rôles were explained as having been caused by hereditary structure, intra-organic stimuli, and extra-organic stimuli. Structural development was thought to be a result of behavior itself. Percepts were defined as constructs which make situations meaningful in the context of a unique, progressive integration of rôles. Systematic thought was considered to be communication between the self and the "generalized other," and so presupposed the socialization of the individual through prior objective communication experiences. For Mead, systematic understanding was the harmonization of evidences from perspectives which pertain to different social rôles. The person plays different parts in social life yet, because he is treated as an individual, must somehow unify the trends which society considers to be contradictory. Thus the individual achieves integrated personality and a definite world view at the same time and through the same stages.

Situational psychology, as developed by such American sociologists as W. I. Thomas, attempts to discover how social factors influence the individual's definition of situations. The person is said to define the goals of his activities with reference to social norms and to those theoretical and technical facilities which his culture provides. In its most extreme development situational psychology treats even personal time and personal space as being cultural artifacts, at least in part. Few social psychologists realize that biological factors, like changes in metabolism, may also affect judgments of time. Some students of behavior believe that geographical and meteorological factors play a part in shap-

ing personal modes of perception and thought. Situational psychology seeks to discover the cultural determinants of different world views, and to discover how in turn world views affect esthetic appreciations and even affect non-esthetic perceptions. Guenther Stern has interpreted the sculptor Rodin's work through categories which are proper to situational psychology, if it be widely conceived. The German school of so-called *Verstehen* (understanding) Psychology has some affinities with situational psychology, but the *Verstehen* viewpoint is more phenomenological in an Hegelian sense, and is less concerned with causal factors.

Robert F. Creegan has suggested that social psychology should be defined as being the sociology of personal behavior. Interpreted in a social frame of reference, personal activity evinces a definite rationale which may be more or less self-consistent or self-contradictory. Some behavior conforms with the conventional ideals of status and status seeking, and so may be called status-referent behavior. Other behavior is pre-conventional. Some very complex human behavior represents a quest for more satisfactory value standards than those provided by the momentary cultural epoch. Similarities and differences between conventional, rebellious, questioning, pre-conventional and other types of behavior in different social orders are sought by social psychology as the sociology of personal behavior. R. F. Creegan, working within this general frame of reference, has attempted to interpret praise, disgust, the comic attitude, the tragic, contempt and several other attitudes which are familiar ones in Western culture as being manifestations of a basic status-referent orientation. Creegan tends to identify this orientation with the source of various inter-group conflicts, and to regard it as being cognitively defective and subject to change by education or by catastrophes which might affect social security.

Finally a frame of reference should be formulated for applied psychology. To date the various branches of applied psychology such as industrial psychology, consulting psychology, educational psychology and others, have no unifying frame of reference. It may be suggested that applied psychology should be conceived to be a component of man's engineering activities. A traditional definition of engineering is that

engineering is the art of organizing and directing men and of controlling the forces and materials of nature for the benefit of the human race. All physical engineering involves human action, usually social in character. All human engineering involves the use of physical energies and processes. Applied psychology contributes to and participates in both types. Psychological is the development of standards for selecting and placing personnel for engineering and industrial work. The laws of learning must be applied in training men to use machines and to cooperate in all working situations. Since concentration upon the job, and consideration for others, involves self discipline which may be irksome, since it usually includes some inhibition of personal desires, all engineering has its problems of worker morale and inter-personal relationships. Society as a whole survives by exploiting natural resources through applying technological knowledge, and social security presupposes cooperation as well as efficiency. The scope of engineering is as wide as the scope of planned human activity, and yet every engineering problem has its psychological aspects. Applied psychology really reaches maturity when its exponents realize these things, and realize the essential functional unity of all the applied branches.

Applied psychology must in turn contribute to theoretical psychology and its frame of reference. Man, the engineer, man, the productive being, must be understood and those who seek to make his productivity more efficient may contribute greatly to the more theoretical task. And since human benefits are the goals of all productive work, the psychological understanding of man must be involved in rationally deciding upon what those goals would be in actual practice. "Benefit," like "value," is relative to the nature of the living being. If the human being's interests correspond to any cosmic trends, then value may be absolute in one sense. That which is determined by the total trend is an absolute, and so applied psychology also might contribute to metapsychological speculation. Most of all, however, it needs some working criteria of human values, and so the applied psychologists should consult with all those of biological and social scientists who can contribute in the quest toward establishing such working criteria.

FRUSTRATION AND AGGRESSION.

—From a systematic standpoint, a behavior sequence may be analyzed in terms of either learning or on-going action. An analysis of its learning characteristics would include such considerations as the amount of reinforcement provided by successful completion of the act, the nature of the discriminations differentially reinforced, the kinds of anticipatory responses established, and the changes in relative habit strengths of the different potential responses to the stimulus conditions present at the time the act started and ended. Clearly, it is of great importance whether the act terminated in a goal response or was met by non-reward or punishment, since the type of terminal act determines whether reinforcement or extinction of antecedent acts occurs. This kind of analysis provides the necessary information about the person's *post-act response potentialities* that must be known to permit prediction of his future behavior.

An equally important systematic problem is that of the antecedent-consequent relations within the action system itself. If a person's response potentialities are known, it becomes necessary

to specify what stimulus conditions will produce what responses. Again the fate of the behavior sequence becomes important, for if it terminates in a goal response there will be a lessened tendency to perform the same actions immediately afterward. But if there is interference, any one of a host of consequences may ensue, depending on the nature of the action and the stimulus conditions obtaining. It was to help bring order into this latter set of relations that the frustration-aggression hypothesis was originally presented (Dollard *et al.*, 1939).

The effects of frustration can best be described in their behavioral setting. The basic unit of molar behavior is an action sequence that terminates in a *goal response*, i.e., a consummatory action that reduces the strength of motivation to perform that specific action. Such responses are reinforcing, or rewarding. The antecedent conditions, both internal and external to the organism, are defined as *instigators* of the behavior sequence. When instigation occurs, the organism must often perform a series of *instrumental* acts before the goal response itself can be made; i.e., it must do things that put it in such appropriate context with the environment that the terminating action can be carried out. For example, a child who is hungry, as indicated by the fact that he has not eaten for several hours, sees bread and jam on a shelf. He climbs on a chair, puts the food on the sink, makes a sandwich, and finally eats it. The hunger is the drive-instigator; the sight of food is a cue stimulus or instigator; the preparations for eating are instrumental acts; and the actual eating is the goal response. It will be noted that the eating puts an end to the child's actions relating to food.

Frustration is any interference with a goal response or with the instrumental acts leading to it. If the child's mother had come in and told him not to eat a sandwich, he would have been frustrated because he was prevented from completing the sequence. The frustration-aggression hypothesis is that *the occurrence of frustration creates an internal instigator to aggression*. In this connection, *aggression* is defined as "an act whose goal response is injury to an organism (or organism-surrogate)." Examples of aggression include such diverse forms of behavior as complaining, hitting, insulting, spreading rumors, cruel joking, swearing, kill-

ing, and even self-demeaning and suicide (aggression directed toward the self.)

It is evident to the most casual observer of human behavior, of course, that every frustration is not immediately followed by aggressive behavior. In other words, the instigation to aggression is not always potent enough to overcome other responses elicited by whatever other instigation exists in the person or his environment at the time of the frustration. The *strength of any instigation* may be defined as the degree to which its response competes successfully with other simultaneously instigated, incompatible responses.

Following a frustration produced by the blocking of an instrumental act, there are often alternative acts the person can perform which will serve equally well to put him in proper position to make his goal response. Some of these may be newly reasoned out actions (progression), while others may be old, previously discarded acts (regression). Or an alternative goal may quickly be sought (substitution). Various other non-aggressive reactions may constitute part of the person's repertory of behavior that can be activated when appropriate instigation exists. Aggression must necessarily compete with all these other actions, and in many instances the strength of instigation to the aggressive reaction is weaker.

Special attention must therefore be given to the factors determining strength of instigation to aggression. There are three main ones that can be stated: (1) strength of instigation to the frustrated response. The more powerful the drive behind the original activity, the greater is the probability that aggression will ensue upon frustration. (2) Degree of interference with the frustrated response. Many kinds of motivated activity can be delayed somewhat, or the amount of reward reduced; frustration may be partial rather than total. (3) Number of frustrated response sequences. Instigation to aggression produced by one frustration may not be sufficient to compete with that of other reactions, but repeated frustration leads to a summation of the instigation produced by each incident, and hence the strength of instigation becomes stronger with an increasing number of frustrations which have not individually produced aggressive actions.

The above principles relate to strength of instigation to aggression only; they do not indi-

cate the factors that determine whether an aggressive act will actually occur. If the strength of instigation to alternative (non-aggressive) acts is held constant, however, there are three factors known to be influential in this respect: (1) the strength of instigation to aggression, as measured by the above relationships. (2) The amount of inhibition of aggression. If aggressive behavior does not remove the frustration (non-reward), or if it meets with counter-aggression from others, or if it is followed by pain, an inhibition of the particular punished act will be established. This relates only to the act itself, not to its instigation. If, on the other hand, the aggression overcomes the frustration, (3) anticipation of reward by aggression will be learned. The greater this anticipation is at a given moment, the greater is the facilitation given to the aggressive behavior, and the greater is the probability of the latter's occurrence.

There are many forms that aggression may take. These vary in respect to both their overt-ness and their directness toward the frustrating agent. The particular kind of aggression that follows a frustrating experience has been shown to depend in part on the amount of punishment anticipated for the different possible acts. In general, if there is high anticipation of punishment for overt aggression, there is a greater probability that nonovert forms such as joking and phantasy will occur.

The strongest instigation is to acts directed against the agent which is perceived as having been responsible for the frustration. Since the frustration-induced instigation to aggression is presumably identical for all frustrations, however, there is generalization of response, and to some degree every frustration produces instigation to every aggressive act in the person's repertory. Hence, if there is sufficiently strong inhibition of the aggressive acts that would be directed toward the frustrating agent, there can be an apparent displacement of the aggression toward other objects. Since the inhibition of the direct aggression is itself a frustration, there is an increased strength of instigation toward the other (displaced) objects. This provides for the appearance of over-determinedness so often noted in the case of displaced aggression.

In this connection it is important to note that aggression may be turned toward the self if all other objects threaten too much counter-aggression. Suicide, masochism, martyrdom, and

self-derogatory acts of many kinds are often examples of this tendency. However, since self-aggression is a relatively painful procedure, there is normally a good deal of inhibition of it, and in its more extreme forms it must be considered a kind of final desperate effort to secure a non-threatening object for aggression.

In some situations, for example in economic depressions, the actual frustrating agent is either impossible to detect or is vested with so much power that no aggression is possible. When whole groups of people displace their aggression toward some single and convenient target (e.g., a group detectably different from the frustrated majority, as Negroes, bankers, Jews, college professors), scape-goating is said to occur. This process, horrifying when observed as a mass phenomenon, is an instance of the collective displacement of aggression by the individuals composing the group.

One final point must be made with reference to the operation of the frustration-aggression relationship in the individual. Aggression is defined as a goal response, and hence one of its characteristics is that the occurrence of aggressive behavior reduces the immediate strength of instigation to aggression. This provides for the phenomenon described by Freud as catharsis. The instigation to aggression has the properties of a drive; it demands an appropriate goal response and will summate with later frustration-induced instigation until such response occurs. Inasmuch as aggressive behavior is widely inhibited in all societies, each individual carries with him at most times an existing instigation which is being constantly strengthened. An outburst of aggressive behavior eventually ensues, and the instigation is reduced. Such reduction eliminates the myriad imperceptible actions, or "tentatives," that are continuously being made in an effort to overcome inhibition and find a safe outlet for the great bulk of instigation to aggression. These tentatives necessarily interfere to some extent with non-aggressive adaptive social behavior, and the person gives the appearance of being tense, irritable, easily distracted. Following his final outburst of aggression (catharsis), however, this interference with adaptive social behavior disappears, leaving him calm, friendly, and efficient in his interaction with others.

The sources of frustration become increas-

ingly social as the child grows up. While it is entirely possible for an adult to be frustrated by his own limitations or by purely physical events, the vast number of secondary drives that involve interaction with other people make it probable that many of his frustrations will arise from a failure of effective social relations. Other persons serve as tools in many behavior sequences, as for instance, showing approval, making love, buying things, etc. If they do not cooperate, frustration results for the person seeking such instrumental compliance.

The reasons for this failure to cooperate may lie in the asker's ineptitude at indicating what he wants, or in the cooperator's inability to provide it. It is evident from the definition of aggression, however, that the cooperator may produce frustration for the asker, simply as a means of aggressing against him. Effective aggression by one person toward another is always a frustration for the latter. If, in such a case, the frustrated asker then aggresses toward the cooperator, the behavior may be called counter-aggression.

The social psychological principle involved may be stated as *aggression elicits counter-aggression*. The dynamics within the individual are the same as all other frustration-aggression relationships; this principle is simply a short-cut statement of a specific application of these to the social interaction of individuals.

From a genetic standpoint, the frustration-aggression relationship may be supposed to develop through the operation of adaptive learning. This aspect of aggressive behavior has not been widely explored, but an extension backward into the life history of the principles that determine the modification of aggressive behavior at adult levels would lead to such a conclusion.

One effect of injury to biological organisms is to make them withdraw from the injurious situation. Another is to elicit in them trial and error activities designed to remove the source of injury. Both these effects appear to be universal, and it is likely that the infant early learns to utilize them in his control of other persons. The infant's crying may at first be a reflex reaction to pain, but he soon discovers that adults not only come to him and remove the sources of his pain when he cries, but that they also express dislike for the noise. Since he secures gratification by the instrumental activity

of crying, this response becomes a secondary goal response and the adults' reactions to the crying become secondary goal objects. There are many other actions the baby can perform that bring about this same reaction from the parents, wetting the bed, sucking his thumb, non-cooperation, refusing to talk or eat, hitting, etc. Such actions are usually elicited in the first instance by a frustration that instigates trial and error efforts to eliminate its source. After a few months' experience with the success of these various techniques, all of them associated with frustration-induced instigation, the child learns to use them regularly for easing whatever pains he may have. In the final stage, the injury of others (aggression) becomes more or less independent of instrumental effort and assumes the role of a secondary goal response in its own right.

Historically, these conceptions have their root in Freud's analysis of the role of frustration in human development. In the early thirties, Dollard began to seek coordinating principles of motivation to assist him in the interpretation of culture conflicts between such social groups as the Southern whites and Negroes. He formalized the basic statement that the fundamental antecedent of aggression is frustration. In 1936, he and a group of psychologists, psychoanalysts, sociologists, and cultural anthropologists were brought together in the staff of the Institute of Human Relations at Yale to develop a systematic science that would bridge the gap

between the individual and his society. *Frustration and Aggression*, an exposition of some of the basic principles given above, and of their interpretive implications for such group phenomena as war, crime and political structure, was the first major publication of this group of collaborators. Subsequent publications have come from many sources and are primarily of a research character designed to test, modify and amplify the hypotheses. A complete bibliography of relevant reports has not been published, but most of the more important ones can be found by reference to the bibliographies of the books and articles listed below.

G

GENETIC PSYCHOLOGY, EXPERIMENTAL.—[The following article attempts to outline major trends in experimental genetic psychology of to-day. The reader is reminded that genetic psychology does not completely coincide with child psychology; from the tremendous amount of work dealing with the psychology of the child only problems and studies have been selected that are concerned with development in its various aspects. For general surveys of the field vid. the following publications: Munn (129), Murchison (130), Nat. Soc. Stud. Ed. (133), Monroe (124), Goodenough (62, 63), Barker-Kounin-Wright (12), Carmichael (31), Werner (180).]

A. GENERAL PROBLEMS

The design of pertinent experiments in genetic psychology depends on the manner in which the concept of development is formulated. The two contrasting approaches to psychological science in general—conveniently labeled the mechanistic and the organismic approach—are reflected in the literature on the development of human behavior. Having existed always side by side, each of the two approaches has dominated for a long time separate areas of child psychology. Non-experimental, mainly clinical and observational studies of development usually championed the notion of "the child as a whole" whereas experimental child psychology naturally was bent on the discovery of elementary detail.

The last decades have witnessed an increasing shift from the mechanistic toward the organismic point of view in the field of experimental genetic psychology. Due to many factors, such as the successful introduction of experimental methods into the psychology of personality, social psychology, and clinical psychology, the emergence of the Gestalt movement, etc., the conviction has been gaining ground that analytical procedure and holistic approach are not mutually exclusive. It therefore seems safe to predict that the gap still existing between ex-

perimental genetic and clinical child psychology will, eventually, be bridged.

Two notions in general seem to underlie the mechanistic conception of many older experimental studies of development: (1) the notion that changes are necessarily continuous and that mental forms, rudimentarily present at birth, unfold by degrees, in merely quantitative fashion; (2) the notion that growth can be defined as a mere increase in complexity, or a gradual accumulation of mental elements.

In recent years, much experimental work has been conducted in support of the conception of qualitative and discontinuous changes during development. Significant advances have been made by research workers who are directing their effort toward the characterization of genetic levels in terms of developmental patterns of organization rather than in terms of aggregates of elementary functions.

Saltatory versus Continuous Changes. The inspection of physical growth curves, of gradually increasing test scores, the observation of steadily rising learning curves lead psychologists to the conclusion that continuity is a basic property of development. In their zest to quantify mental life by analogy to physical events they became quite oblivious of the fact that discontinuity rather than continuity is a basic characteristic of biological, and even physical activity. "All our experience," says Lecomte Du Nouy in his remarkable book on *Biological Time*, "leads to the admission that continuity exists nowhere, and that one of the rôles of consciousness is to manufacture continuity from discontinuity" (48). All the principal facts of physiology support this view: the existence of a threshold of nerve excitation, absolute and relative, the propagation along the nerve in terms of electrochemical explosions, the all-or-none law of nerve stimulation, and various other equally well known facts points to abruptness, selectiveness as a basic sign of life processes.

Continuity as a property of development has been "manufactured" by a twofold manner of

handling the data: (a) by not only measuring, but also interpreting development solely in terms of overt achievement; (b) by averaging individual, abrupt scores and thus obtaining a composite curve that pictures continuous growth.

The number of child psychologists that are not entirely satisfied with this method of approach and with the results obtained by it, is increasing. They see the lack of proportion between the elaborate measurements of a great many data and the often trite conclusions derived from them. Only little is added to our understanding of development by finding that the number of words, the length of sentences, the span of attention, the ability to reason, etc., rises steadily with age. These psychologists are also certain that the leaps and bounds of individual curves, often blotted out by the emphasis on achievement and on group scores, are significant symptoms of processual changes underlying overt performances. The modern genetic analysis is beginning to take cognizance of the emergence of novel functions, of the creative reorganization of mental elements that take place during growth.

Even within the area of *physical development* which many psychologists look upon as the prototype of continuous growth, the change of emphasis is clearly noticeable. Developmental anatomists like Wingate Todd advocate a shift away from purely quantitative measurements of isolated somatic elements toward examination of changing textures and configurational patterns. Though it might not be possible to subject these patterns to perfect quantification they can be profitably ordered in sequences of maturation (52). If individual curves of physical growth are combined, not in regard to average ages but according to their shape, that is to their crests and troughs, discontinuous changes of growth rate become clearly visible (120, 121, 162).

Investigators such as Honzik, Freeman Flory, a.o., studying *mental growth* longitudinally, by individual curves, found rates of growth consistent only over short periods (78, 53).

The disagreement that still exists between those who find evidence only for continuity, and those who argue for discontinuity seems to be less based on differences of techniques used than on the general methodological approaches

that direct the formulation of the experimental problems and procedures. McGraw, for instance, contended that infantile motor development is an entirely gradual and continuous event; this conclusion she drew after having observed two infants five days every week for many months (114). On the other hand, M. Shirley found considerable evidence that many new behavior items emerge, full-fledged, by fits and starts (160). Her inferences were based on examinations of 25 infants, so closely spaced as to make observation virtually continuous, and on daily records kept by the mothers. The difference between the results does not seem to be caused, as it has been argued, by the wider spacing of Shirley's observational periods as compared with McGraw's; it springs from the two experimenters' different aspects of observation. Results derived from an analysis of *elementary functions*, and results, coming from observation of *patterns*, cannot easily be reconciled.

Genetic Aspects of Mental Organization. For those who are searching for genetic patterns the analysis of mental organization at different developmental levels becomes a central task. In order to determine the changing nature of mental organization one must have a framework of genetic concepts. Generally, organic development can be defined as increasing differentiation and centralization—or hierarchic integration. We have attempted previously to show that less differentiated forms of organization are more "syncretic," more "diffuse," more "rigid"; they are also less hierarchically integrated (180, p. 53).

If several mental functions, which would appear as distinct from each other at a more mature level, are merged into one activity, we may speak of a "*syncretic*" phenomenon. An illustration is a dream image, containing several meanings to the dreamer. A "*diffuse*" structure lacks articulation, that is, discrete parts related strictly to each other and the whole. Primitive drawings of children are examples of diffuse or "global" forms. *Hierarchic integration* points to the domination or control of motor, sensory or emotional behavior by higher functions, such as concept formation and reasoning.

Evidence is accumulating that, in accordance with these laws of development, organization is *less differentiated*, more homogeneous at earlier levels than at more advanced stages. This seems to hold even for the most general *mind-body relationships*.

tive activity indicate an increase of the former functions up to six months followed by a sharp decline, and a steady increase of the latter function. In other words, a shift of dominance has occurred, after the first half year, from sensory-motor activity to functions of higher integrative power. Richards and Nelson, studying 80 infants, found a similar shift of dominance from a "general motor" toward a "mental" factor of intellectual alertness (151).

(2) A function may gain a high degree of integrating power because of its changing relation to the total personality pattern of the growing organism. Depending on the need—or motivational, system of personality, certain functions may gradually acquire a central rôle. Shifts of dominance of this sort correspond with the process of individuation and therefore are an important topic of a genetic psychology of individual differences as well as personality in general.

Two illustrations may be presented that demonstrate clearly the emergence of integrating factors within the growing personality.

Razran, studying simple conditioned responses in children found the susceptibility for conditioning increasing up to five years of age; from there on the susceptibility decreased. "The decrease in the speed of conditioning" concludes Razran, "is due to the emergence of a new factor . . . the children become more 'unwilling' to be conditioned." In the opinion of Razran, this new factor is a central attitudinal one: making its first appearance at the year level of 3-5, it is most probably connected with the child's growing capacity for conscious control (146).

Another example is afforded by a widely investigated topic, namely the development of color and form abstraction. As is well known, children, between 3 and 6 years of age, group colored geometrical shapes together more frequently on the basis of similarity of color than of form. Older children increasingly more often classify according to shape (180, p. 234). However, superimposed upon the general development is a trend toward individuation. This trend of individuation results in differences between two types, sometimes called the "form perceivers" and the "color perceivers." According to Tobie, typical attitudes of this sort become more and more effective, starting at the early school age (174). From that time on

tendencies in abstraction depend increasingly less on the general maturity level because integrating and consistent personality traits are developing which hierarchically control the individualized patterns of personality.

The final ambitious goal of experimental genetic research directed toward the analysis of organizational pattern is a comprehensive theory of *ontogenetic phases*. The possible existence of such phases is unwittingly admitted even by those writers who, though insisting on continuity as an intrinsic property of development, are, at the same time, willing to accept a division into genetic periods such as early and late infancy, childhood, prepuberty, adolescence, and adulthood.

Some writers such as the psychoanalysts, Piaget, Ch. Buehler, Spranger, a.o., have attempted to outline ontogenetic epochs and to interpret their organismic meaning (50, 26).

Freud's early stages of libidinal organization (oral-anal-genital) are well-known. So are his genetic stages emerging from the dynamic interrelationship between the principle of pleasure and the principle of reality (Infantile and early childhood: ruled mainly by principle of pleasure; later childhood: repression, sexual latency, and early sublimation of sex drives, early superego development; puberty: peak of libido sublimation; adolescence: integration of sublimated libido and reborn sex drives, maturation of superego) (50). Entirely different in scope is the genetic scheme offered by Ch. Buehler. Based mainly on the experimental findings of the Vienna laboratory, Ch. Buehler distinguishes five phases, each of which are characterized by a change in the relation between the growing self and the growing reality (26). Piaget's attempts are directed toward the distinction of stages with reference to specific rather than general activity, such as causal reasoning, or moral judgment. Some of his distinctions will be discussed later.

All these various interpretations contain probably a greater amount of hypothetical elements than the available data warrant; but they function as valuable stimulants in an area in which the danger of an overflow of research that lacks principal ideas is, perhaps, greater than in any other field of psychology.

Developmental Laws and Learning. The general laws of development, as stated above, transcend the distinction between maturation and learning. Any true learning consists essentially in the reorganization of behavior in terms of

increased differentiation and integration. Many neurophysiologists of to-day hold that, physiologically, the processes of maturation and learning are of the same nature. "The conception," remarks Coghill, "that a neurone grows during a period of maturation, and then ceases to grow and becomes simply a conduction in a fixed mechanism, is erroneous, and wholly inadequate to account for the function of the nervous system as a mechanism of learning" (34, p. 83).

Notwithstanding the basic identity of the processes of maturation and learning, there remains still the problem of the relation between innate development and development by practice through external stimulation. Experiments have been designed to investigate the effect of maturation by comparing children reared under conditions of restricted activity and stimulation with normally trained control subjects (44, 76, 114). Gesell, employing identical twins as experimental subjects convincingly demonstrated the importance of maturation in early development. The twins' behavior in prehending pellets and in other situations conveyed an almost uncanny degree of identity in the details of posture attitude, hand attitude, and mechanism of grasp (58). Another interesting illustration of innate development is afforded in an ethnopsychological experiment by Danzinger and Frankl (38). Albanian children are so bandaged in their cradle during the first year that they can move neither hand nor foot. Unbound for experimental purposes they were unable at first to handle anything; but during the next two hours they covered all those steps of manipulation for which children of our civilization require many months.

The results of the many experiments conducted in this field lead to the conclusion that the relation between maturational and practice factors varies depending on the level of organization, on the biological relevance, etc. The less primitive an activity is, or the farther it is removed from the sphere of biologically essential performances, the more important becomes the factor of practice. But even for the highest forms of activity experiments have confirmed the educational principle: that training is more successful with those children whose maturity corresponds with the activity in which they are being trained; it is less successful with children who are below that maturity level (27, 86).

B. SPECIFIC MENTAL PROCESSES

1. *Motor Action Patterns and Their Development.* The developmental law of increasing differentiation and hierarchic integration is clearly observable in the field of motor action.

Experimental evidence brought forward by the students of human fetus behavior (Minkowsky, Hooker, a.o.) has given little support to the older view that action patterns develop primarily through the synthesis of specific reflexes (124, 79). The primary response is "diffuse" or "global" and is perhaps best described as a *focalized mass reaction*. Clearly seen on younger human fetuses, it is a response that is most intense close to the stimulated part of the body; it fades off toward the more remote bodily regions.

Further development seems to occur in two directions. One leads to individuation, or specification of the focalized mass response. The other leads to the hierarchic integration of several focalized responses, that, initially are little coordinated with reference to one another (180, 82).

Hooker's work furnishes an excellent illustration of the process of *individuation* in the human fetus. The young fetus of eight weeks responds to facial stimulation with a neck- and upper-trunk movement. Later on, the movement expands caudally. By fourteen weeks, the massive movements have become circumscribed and specified; the fetus responds now with a number of discrete and specific movements (79). The process of individuation has been observed in various activities of the neonate, such as sucking, smiling, grasping (16, 43). Sucking, originally involving many of the facial muscles, narrows down eventually to lip movements. Similarly, during the first six months, grasping includes the activity of the whole body.

The increase in *coordination*, or integration, has been found to be achieved in two ways: (a) by inner differentiation within a hitherto diffuse or massive movement; (b) by synthesis of several specific movements into one differentiated activity. Halverson's cinematic studies of infantile prehension present excellent illustrations of the first type of development. During the first year, prehension patterns change, following each other in this sequence: (1) simple palmar grasp; (2) palmar grasp and thumb opposition;

(3) fingertip grasping. This trend is again noticeable in the genetic shift of dominance from the arm as a whole toward the distal parts: in early infancy the hand functions as an extension of the arm, later on the forefinger and thumb govern the course of arm movements (67).

Increase of coordination of relatively independent movements has been studied by Sherman, Ch. Buchler, a.o. These authors analyzed the increasingly more efficient movements of the infants in their attempt to remove disagreeable pressure applied to the face (158, 27).

Since it forms an indivisible whole, primitive motor action lacks plastic adaptability. Experimental studies by Lewin, Gottschaldt, Werner, a.o., suggest an inverse relationship of rigidity to chronological and mental age (107, 64, 182).¹

Pertaining to the growth of adaptive behavior is a further significant development, namely, the growing differentiation between the organism and its objective environment. The primitively acting organism is intimately bound up with the concrete situation: the infant and its environment are almost one; his actions are immediate and concrete, lacking the guidance that comes from the acknowledgment of the objective qualities of the world.

Thus, decrease of immediacy of action signals a development through which the organism gains greater freedom of movement. This genesis has been studied by experimental devices that test the degree of indirectness of behavior. Following the lead of Koehler's work with apes, Gottschaldt, Alpert, Lippmann and Bogen, a.o., have reported on the rising ability of the child to master the environment by indirect action; this involves the use of circuitous routes, instruments, and the ability to delay and to plan (64, 2, 20, 108).

Growing spontaneity of action is still another indication of the differentiation of the child organism and his objective environment. Seen neurophysiologically, the great motor systems that are little subjected to voluntary control—the autonomic and the extrapyramidal systems—seem to precede genetically the voluntary system. The very young child is "stimulus-bound" (Goldstein); he is passively subjected to the stimuli of the surroundings. During the first year, according to Buchler, spontaneous, that is, searching and exploratory movements increase from 0 to 30% of all movements registered.

Strong stimuli of sound and light at first cannot be mastered by the organism: hence he reacts negatively to these stimuli by crying, turning away, etc. Later, at about six months, the predominantly negative responses change to predominantly positive reactions; this is an indication that the child organism has learned to "digest" intense stimulation (27). Many other reflex-like responses undergo a similar change. For instance, the Moro startle pattern, at first mainly extensor in nature, is later replaced by a primarily flexor pattern that presages movements of embrace. Similarly, the Babinski reflex of the infant develops into the plantar reflex of the older child (32, 79, 60).

On the objective side, we observe a growing ability to act with reference to the material characteristics of things and situations. According to Buchler and Kautsky, children, from the end of the first year on, become more and more aware of the specific material nature of things; their ability of adequately handling material (sand, blocks) grows considerably during the second and third year (27).

We may add that genetic characteristics of motor action can be observed also in experiments on primitivation. Dembo, Lewin, Barker, Patrick, a.o., have shown that a frustrating situation may cause a momentary regression of motor behavior (11, 139). Such development in reverse leads to stages of decreased differentiation and hierarchic organization. In their recent work, Barker, Dembo and Lewin achieved frustration with children, 2½ to 5 years of age, by placing a transparent screen between the playing child and a number of desirable play objects. The effect of the frustration could be determined in terms of regression to a genetically lower stage of play measured in points of constructiveness.

2. *Emotional Behavior.* Experimental studies have brought forward much evidence for developmental changes in emotional behavior similar to those discussed in the previous section. Main genetic trends will be briefly outlined.²

(a) First, there has been observed a genetic change from "syncretic" (bodily-motor-affective) and massive behavior to specifically emotional reactions. One of the signs of this trend is the decrease of overtness ("internalization") of the emotional response. Bayley, Blatz, Lippmann, a.o., studied the diminishing rate of crying during early age (13, 19, 108). A compari-

son of Goodenough's records on young children with the behavior of older subjects demonstrate the decrease with age of the frequency of public display of anger (61). H. E. Jones, using the galvanometric method with infants and preschool children, found a genetic trend in the direction of inhibition of overt (somatic) expression concomitant with an intensification of visceral responses (93).³

(b) Closely connected with this development is the increasing differentiation of the emotional content. K. Bridges, in her well-known work, has generalized the genesis of emotions from a generalized undifferentiated affect which she calls "excitement" (22). Differentiation of emotional expressions begins at a rather early infantile stage. Refined techniques, such as the use of the oscillograph by Klein, Gray and Jeffress, made it possible to distinguish the crying patterns of hunger, fear, and rage at an age level at which earlier work, employing cruder methods of observation, did not find evidence of differences of emotional expression (97, p. 7).

(c) Increase in hierarchic integration of emotional behavior is another important genetic trend. Intellectualization, that is, domination of emotions by higher functions advances with the growing child. Primitive emotions are uncoordinated, blind, momentary outbursts. Emotions of growing children are short lived and ever-shifting events. According to Jersild after-effects of anger were almost twice as frequent and prolonged in children over four years of age, as compared with those of two-year-olds (87). Goodenough, Blatz, a.o., have analyzed the increasing ability of the child to react adaptively in annoyance producing situations (61, 19). The genetic order by which emotional patterns of lower degree of adaptability are placed by those which are controlled by higher functions is excellently illustrated by Blatz' and Millichamps' study on infants (20). In the beginning, massive unadapted outbursts were found to be the rule. As the infants advanced in age, their effort directed toward the removal of an unpleasant situation expressed itself in increasingly higher forms of integrated behavior; first, adaptation occurs entirely through locomotor activity (turning or running away, etc.), later on, at about two years of age, symbolic forms of expression (hiding face, verbalization) are added to the means of adjustment. Here, as in other areas, the development re-

peats itself at higher levels: for instance, in social conflict situations, arising among school-children, crying and shouting, as expressions of helplessness, decrease and become replaced more and more by the use of adaptive language (90).

Another aspect of this development pertains to the causes of emotions. The first causes are immediate and concrete. Fear, as Jersild has shown, is created in the young infant by disturbing events, such as loud noises which act in an immediate and direct manner upon the child. As the child grows older, factors of a non-immediate, imaginative, anticipatory nature become more prominent. Between the ages of 23 and 71 months, the fears of Jersild's subjects caused mainly by immediate and concrete experiences such as loud noises, pain, loss of support, decreased, whereas fears induced by imaginary creatures, darkness, and dreams, increased (88, 89). The growing effectiveness of potential danger has been studied by Jones. Jones' two-year-old subjects showed no fear if a snake was suddenly exposed before their eyes; two- to four-year-olds demonstrated increasingly more and more cautious apprehension; children over four years of age exhibited definite fear at the sight of the snake (91). The positive correlation between these anticipatory forms of fear and IQ is a further indication of the mounting intellectual control (88).

3. *Sensory-Motor and Perceptual Processes*

As in the foregoing sections, developmental trends as observed in experimental situations shall be rather summarily discussed.

Increase in Sensory-Motor and Perceptual Articulation. Experiments on drawing, writing, singing, formboard performances, etc., have shown that development proceeds from global, unanalyzed units to forms of organization, the essential feature of which is a definiteness of parts that stand in clear relationship to one another and to the whole (180).

A young child, asked to copy a geometrical pattern or repeat a tone pattern by singing, will almost invariably by his errors reveal a tendency toward a less differentiated form (183). Globally organized forms, such as continuous circular shapes, are among the first patterns that the child is able to construct correctly. Volkelt has shown that a young child is likely to represent a square or a cylinder by a circle (180, p. 118). Hildreth has published the typical first attempts of five-year-olds in number and letter

construction (75). The errors lie all in the direction of simplification, symmetrization, etc.; in brief, in a de-differentiation of the original. We have analyzed recently the development of visuo-motor performances on a "marble-board" (181, 186). The child was requested to copy mosaic patterns by putting marbles into some of the (100) holes of the board. This is what we found: younger children placed marbles in continuous sequences of holes. With increasing mental age the "continuity" type became replaced by a "construction" type. Here the mosaic patterns were built by moves which successively enclosed the form from several sides; thus the continuity of the earlier performance was broken up into part sequences. The younger child followed the total outline; the older child divided each pattern into natural parts which stood in definite relationship to one another.⁴ Heiss and Sander, by means of an ingenious block-building experiment proved that the younger the child the less is he able to analyze a perceptual whole with reference to its parts (180, p. 117).

Differentiation as Increase in Specificity. Primal forms of perception are less specific, more "syncretic." This means—according to the definition given at the beginning of this survey—that perceptual and non-perceptual functions, distinguished from each other at a more mature state, are at an earlier stage fused into one undifferentiated phenomenon. Primitive perceptions are, for instance, expressive or "physiognomic," because emotional, kinaesthetic factors and the like are intimately merged with sensory data. Experiments on perception, showing a high degree of physiognomic content, have been performed by Muchow, Gantschewa, Volkelt, and the writer (180, p. 90). The first differentiation of colors is based probably as much upon the sensory factors as on their affective values. Goldstein and Rosenthal studying cerebellar patients found clinical evidence suggesting that expressive color characteristics such as "warm" and "cold" are founded on specific bodily reactions to certain color stimuli (60). The results of a study of an early chromatic development by Staples seems to support these suggestions. Miss Staples found that up to the age of 15 months, children behaved differentially to two groups of colors: the red-yellow group appeared significantly more preferred than the blue-green group (168).

Another class of syncretic phenomena are the synaesthetic experiences. Older investigations by Bleuler and Lehmann, and more recent ones by Révész and by Zietz indicate that synaesthesia is relatively frequent in childhood and regresses with advancing age (180, p. 88).

Hierarchical Integration During Perceptual Development. With increasing age changes of perceptual organization occur due to an increase in domination of sensory processes by higher functions. On primitive levels the organism responds discriminately to sensory stimuli in terms of bodily (sensory-motor) reactions. Discrimination in terms of perceptually observed relationship, as operating in a color matching situation, obviously represents a later developmental stage. Still later the child becomes capable of fixating definitely the various qualities of the perceptual field by name-giving activity. Finally, abstract, classificatory concepts emerge that again may reorganize, in a novel manner, the perceptual field. Thus discrimination is not a unitary process; its development implies the successive emergence of quite different function patterns as the child moves from one genetic level to another. As Cook has shown, between the ages of one and a half to six years, the correct performances in a color matching situation increase from 45% to almost 100%, whereas in the naming of these colors the increase is from 25% to only 62% (36). Various experiments suggest that sensory discrimination on a non-verbal level develops early and, after having reached a peak in childhood, may possibly even decrease. Peckham, using a non-verbal form of Snellen's test, concluded that children of only 21 to 62 months possess a visual acuity similar in range to that of adults (140). According to Peters brightness sensitivity reaches its peak at about 14 years of age (180, p. 98). The peak for tactile sensitivity seems to be attained much earlier; Friedmann found even a decline of the tactile threshold after six to eight years of age (54).

This latter result seems to be in keeping with another group of findings; viz., a shift of dominance, for certain situations around eight years, from tactile-kinaesthetic (contact-receptive) to visual (distance-receptive) factors. We concluded from our results with the marble-board test that the performance of younger children was guided by predominantly tactual-kinaesthetic factors; with older children visual form

factors became increasingly more dominant. This shift of dominance occurred around the eight to nine year level (181). A similar shift was found by us in an experiment in which the children had to tap four squares in a certain order. The order was indicated previously by the experimenter in two ways: by tapping in one series, and by light signals in the other (179). It is probable that the more abstract the task, the later during development, the shift may be expected to occur. Experiments performed by Renshaw obviously dealt with such an abstract situation. Children were requested to point, with open or closed eyes to an area on their skin, that had been previously touched by the experimenter. He found a shift toward visual dominance occurring at about thirteen years of age (149).

The development of *space and time* experiences in the child affords excellent illustrations of the genetic law of hierarchization or intellectualization on the perceptual field. Experiments by Gordon, Piaget, Werner, E. Meyer and others have shown that space is apprehended primarily through sensory-motor activity; it is an "egocentric space-of action" (180, p. 172). During early childhood, according to Piaget, the child begins to perceive spatial relationships between objects, more or less independent of his own bodily movements. On the other hand, for many spatial relationships, such as left and right, in front of, behind, the frame of reference remains for a long time the child's own body. A still further reorganization occurs when space perception becomes subordinated to abstract, universal concepts (175). The recent ingenious experiments by E. Meyer brought new evidence in support of the interpretation of space development as outlined here (122).⁶

Another important topic of perceptual development concerns the apprehension of objects according to their *constant* properties. Animals as well as human beings are able to perceive qualities of objects such as size, color, form as relatively constant properties by making "corrections" for the variation caused by illumination, distance, or position. Chalk looks white whether seen at bright daylight or at dusk. The trend of the organism to keep properties of visual objects constant is evident at at least three increasingly higher levels. The most primitive level is the physiological adaptation to variation of illumination. The main mechanism

of this sort in man is the light and dark adaptation of the eye. This peripheral-autonomic adaptation is unstable with the new-born but develops very rapidly (40). The physiological capacity for making proper allowances for the change of illumination has been shown to exist already on a relatively low biological level. Some fishes, for instance, change the coloration of the skin in response to light; this response is dependent not upon the absolute intensity of the light rays reaching the eyes but on the ratio between these rays and the incident illumination (109). Such instances suggest that neither in man nor in fish is the physiological mechanism that corrects illumination effects an act of judgment or even of perceptual awareness. A higher level, however, requires the perceptual relation of the light reflected from the surface of objects to the total illumination of the field. The development of this "perceptual constancy" is slower than that of physiological light adaptation. However, as Brunswik and his collaborators have shown, perceptual constancy of brightness, color, shape, and size, reaches its peak along before adulthood; it declines at about fourteen to fifteen years of age (24). This decline is most likely due to reorganization on a higher plane: conceptual operations—judgments, comparisons, mental measurements—emerge as factors of control and replace partly the concrete, perceptual apprehension of the world.

4. Memorization

Many genetic experiments have been performed in this field the results of which, though not as conclusive as in other areas, are highly suggestive for a developmental theory of memory.

Development of Memory as an Increase in Organization. As one would expect, the capacity for retention has been found to increase with age during childhood.⁷ According to Starr, to the Terman-Merrill revision of the Stanford-Binet test, a.o., the normal memory span increases steadily between $2\frac{1}{2}$ to 10 years of age from two to six digits. Also quite obvious are the general findings that memory span varies with the material presented. What is the cause of this increase? We know at least one of the principal causal factors; viz., the growing capacity of the child to organize material to be retained. The younger child tends to apprehend and to reproduce the material in continuous,

chain-like wholes, the older child, in patterns in which parts are related to one another and to the whole. One of our experiments with children two to ten years of age seems to illustrate well the effect of organization on span of attention. If presented with a number of digits greatly exceeding their capacity for retention, the younger children performed far below their normal memory span; older children and adults were able to retain a number of digits closer to their individual capacity. The younger children broke down, obviously, because they were unable to build a continuous whole under these circumstances, whereas older people were capable of gathering discrete items for retention.

Factors of organization seem to be related also to the *delay* of responses. Memory traces are more stable the better they are organized (Kochler, Katona); therefore, they are less easily disturbed by interfering stimuli (98). Hunter, Miles, Skalet, Buehler showed that maximum delay increases in organisms, phylogenetically as well as ontogenetically (129, p. 337; 123, 163, 27).

Development of Memory as an Increase in Specificity. Jaensch's analyses of eidetic phenomena suggest that memory image and perception are less differentiated from one another on lower as compared with higher levels. Eidetic phenomena possess certain properties of sensory as well as image phenomena. These syncretic phenomena seem to be relatively common with children, decreasing in frequency greatly around puberty (85, 102).

The trend toward specialization is noticeable also with reference to material types of memory. Most psychologists of to-day probably agree that, at least in the adult, a general memory factor hardly exists. There are almost as many "memories" as there are areas of mental operations. However, if one descends the ontogenetic scale, one should expect a closer relationship between the various areas of memory. Some experimental evidence has been brought forward in support of such conclusion. Anastasi, for instance, found practically no correlation between immediate memory for various visual material, vocabulary, and number operations at the college level. On the other hand, Bryan reported a high correlation between these faculties at the preschool level (9, 3).

Increase in Hierarchic Integration: Genetic Shift in Memory Functions. Brunswik, Gold-

scheider and Pilek performed a comprehensive investigation of the qualitative changes of memory that occur during mental growth (25). They examined experimentally the growth curves of the following forms of memory:

(a) *Memory for Concrete, Digit-Like Material:* One series consisted of nine unrelated movements, such as hand clapping, lifting arms, making a bow; another series contained nine colors; a third, nine simple geometrical forms. The score consisted of the number of correctly reproduced items.

(b) *Memory for Concrete Relationship:* Here, the same material as in (a) was used; but the score pertained to the correctness of sequence of items.

(c) *Memory for Logically Apprehended Material:* Stories for instance, presented by 12 pictures, had to be verbally reproduced.

The growth curves for the three forms of memory have been found to differ significantly, indicating genetic shifts of memory function during development. The curves for discrete, concrete digits increase up to ten to twelve years, declining somewhat after that age. Curves for concrete relations show a considerable rise up to fourteen years; after fourteen years the increase is steady but slow. Curves for logically apprehended material rise slowly till twelve to fourteen years and rapidly during adolescence.

Earlier work by Winch and McGeoch also seem to be related to the problem of memory levels. In Winch's experiment children were presented with a simple picture; the score consisted in the number of items recalled. Winch reported a peak of the growth curves for these concrete items at about seven to eight years of age (188). McGeoch used three types of material on children nine to fourteen years of age: (a) cards picturing simple objects; (b) a picture entitled "the disputed case"; (c) a carefully rehearsed event. Memory for single concrete objects (a) improved up to twelve years; the recall scores for the picture, and the event (b, c) were found to rise steadily. The scores for the report on the event showed a definite spurt between twelve and fourteen years of age (113).

The various experimental results, though not conclusive, indicate a shift during development in terms of the replacement of a lower memory function by a higher one.

5. Concept Formation and Reasoning

a. *Concept Formation.* In no area of genetic

psychology is the controversy over facts and interpretations as intense as in that of children's thought. The disagreement pertains to basic questions such as whether children's thinking develops gradually or in spurts, whether the difference between childlike and adult reasoning is one of degree or quality.

In terms of "achievement" only, and particularly when results are based on average scores taken from a great number of subjects, a steady increase in thinking efficiency is observable. However, analyses on the achievement level only are apt to obscure specific changes of the processes that underlie the achievements (178).

A good illustration is afforded by the development of abstraction, as studied through sorting tests. Here the child is requested to group a number of objects, or figures, of different sizes, shapes, and color. Results of such experiments, plotted in form of a developmental curve, indicate a quantitative increase in the classifying ability. But the analysis has to go further before one can give a satisfactory interpretation of the psychological factors involved in the development. Such further analysis has been performed by Weigl, Usnadze, J. Thompson, a.o. (180, p. 239; 173). The results indicate important changes that occur in the psychological processes involved in sorting. According to Usnadze, the young child is able to group according to only one category (size, color, etc.). Moreover, there is little freedom of choice in this "one-track-abstraction." Certain conspicuous concrete properties of the objects seem to force the child to unite visually the objects. There seems to come together, almost automatically, the blue objects, the yellow ones, the green ones, etc. This perceptual cohesion between objects on the basis of one category prevents the child from rearranging the field in terms of other properties. A deliberate shift from one category of grouping (from color to shape for instance) occurs only with older children; it involves processual changes, proceeding from "primitive abstraction" closely allied to sensory organization toward an abstraction guided by deliberately selected categories such as size or color. If this interpretation be correct, the development of abstraction cannot be defined simply as gradual. Another illustration of the genesis of abstraction, with processual changes similar to those occurring in classification experiments can be found in the develop-

ment of the number idea. Number in its most primitive form is intimately related to body activity. The fingers in particular present a primordial visuo-kinaesthetic number schema. We have shown recently that a definite relationship exists between the development of the number concept and that of the "finger schema" (184).⁸ The next important step involves the emergence of "concrete numbers"; that is, numbers given as perceptually organized units. We have conducted experiments that suggest a close relationship between the ability to apprehend optical dot configurations and the ability to operate with numbers (185). Still another processual change occurs during the transition from concrete numbers to abstract number concepts.

6. Reasoning

Syncretism (Concreteness). In spite of the violent controversy over many essential traits of childlike reasoning, there is agreement on some of these traits. For once, there is agreement as to the concreteness of lower forms of reasoning. In our own terminology less mature forms of thought are more syncretic, that is, thinking is closely bound to emotional, sensory-motor, and perceptual activity. The young child does not apprehend abstract concepts, or general laws of causation. Experiments performed by Piaget, Raspe, Muchow, Werner, Huang, Deutsche, Heidbreder and others give us some insight into the development of causal reasoning (142, 143, 180, 80, 81, 46, 72, 73, 104). A standard procedure consists in the performance of a simple experiment in physics before the child. For instance, the experimenter cuts a sheet of paper into two equal parts; he leaves one piece smooth and presses the other into a little ball. He then drops both pieces simultaneously to the floor, and asks the child to explain the greater falling speed of the paper ball. Younger children did not distinguish between mere description and explanation ("the little ball falls 'cause you crumpled it"). On a higher level the child apprehends some of the specific, concrete conditions ("it falls quicker because it's heavier"). Experimental devices of this sort make it possible to analyze the development toward higher forms of reasoning in terms of universal, abstract, and necessary causes. Even a group experiment, such as the one performed by Deutsche, and that, in regard to technique, is

open to severe criticism, shows the development from a "phenomenalistic" type of explanation to abstract reasoning (46).

Logical inferences have been studied genetically by Stern, Hazlitt, Piaget, Strasheim, Laycock, H. T. Muller, and others (170, 70, 143, 171, 105, 128). Most authors agree that inferences can be formed at a very early age; however, these operations are often difficult to discern because of their extreme concreteness. W. Stern holds that primitive forms of inference are neither inductions nor deductions; they are "transductions"; that is, transitions from one concrete isolated judgment to another coordinate single judgment. Syllogistic reasoning in particular has been studied rather recently by Muller. Employing subjects ranging in age from seven to seventeen years, Muller found that younger children tend to represent the premises by imagining concrete situations, a tendency that diminishes with increasing age (128).

Strasheim's extremely ingenious experiments deal with the application of previously learned problem solutions to new situations. Strasheim was able to distinguish between two developmental stages: at the "perceptual stage" the child apprehends a relationship necessary for the solution in intimate contact with the concrete elements of the presented situation; thus, the relationship is available for transfer only if the new situation contains similar concrete elements. At a higher genetic stage the relationships are definitely abstracted, and are therefore most effective for future transfer or "education" (171).⁹

These experiments demonstrate that thinking develops from syncretic forms to forms that are more or less detached from perceptual and emotional functions. Other experiments are especially devoted to the genetic study of hierarchic concept formation. Many methods have been devised for this purpose, such as the technique of definition (Barnes), the method of matching of objective relationships that vary in the degree of hierarchical order (Line), the technique of sorting objects representative of concepts (Welch), and many others (12a, 107b, 177).

Lack of Articulation. Many genetic psychologists agree also on another trait of child thought, probably closely linked with that of concreteness. This trait concerns the formal structure of thinking. The structure of thought shows little articulation; that is, the young child tends

to reason either in terms of indivisible thought units, or in a chainlike, associative fashion. Gottschaldt, Lewin, and others demonstrated experimentally the rigid totality nature of primitive problem solving behavior (64, 107). To illustrate: a young child had learned to use a stick to draw toward him objects that lay outside of a fenced-in area. When the whole arrangement was moved to another corner some of the least mature children continued to run to the previously used corner and tried in vain to reach the object.

Experimenters have noticed also another peculiarity of the problem solving behavior in young children: a lack of the conception of the goal as a centralizing factor with reference to which the various elements of a more mature procedure are integrated. This difference between lower and higher forms of reasoning behavior has been variously described as "paratactic" versus "syntactic," as "associative" versus "planful," as "chain-type" versus "goal-related" behavior. This difference is well illustrated by block-building experiments. Very young children concentrate on each single placement of one block after another; older children construct in terms of larger units to which small steps are subordinated. According to Gottschaldt's analysis immature children, presented with a lengthy task, lack the feeling for the lessening distance of the goal, a feeling that in older children changes with every step as the action approaches closer and closer to fulfillment (180, p. 208).

The synthesis of two experiences learned singly is difficult for an individual who acts in terms of chains of rigid action units. According to N. Maier the ability to unite into a novel experience two previously learned experiences is a function of age (115, 116). Maier's assertion that associative learning is the predominant intellectual activity of the young child is in accord with Strasheim's conclusion. This author claims that "bare retentivity or its special form, associative reproduction, plays by far the greatest part in the young child's mental life. . . . The fact that this is the more primitive stage explains to us why there is a constant tendency to relapse into it, even when the later stage has been attained" (171, p. 208).

The Problem of Qualitative Stages of Reasoning. Are there, during development, observable patterns of reasoning sufficiently distinct from

one another to justify an interpretation in terms of genetic stages?

As discussed before, if we restrict our efforts to the calculation of mean age scores and developmental curves of achievement, the essential goal of genetic psychology, viz., the understanding of the processes of growth can never be achieved. The concept of the child as an imperfect adult may be sufficient for practical applications, such as measuring the mental or educational status; it seems, however, wholly inadequate as a guiding concept in an integrated analysis. The problem of genetic levels is intimately linked with this argumentation: one cannot logically believe the child to be more than an imperfect adult and, at the same time, discard the concept of organizational levels.

At this point it might be advantageous to discuss some of the misconceptions about the problem of qualitative levels of reasoning that have arisen in recent experimental literature.

(1) The genetic concept of qualitative differences has been criticized for the reason that adults often display behavior similar to that found in children. This seems to be the belief of Abel, Deshaies, Cameron, *a.o.* (1, 45). However, the demonstration of primitive behavior by adults has hardly ever been overlooked by those who advocate qualitative levels: on the contrary, it has given rise to important considerations of the following sort: (a) Developmental sequences repeat themselves at various stages of maturity. (b) Primitive levels do not completely disappear during development, but become merely subordinated to higher forms of activity. Only because of this fact is it possible to conduct experiments on primitivation in adults; these experiments were of great help in the study of qualitatively different levels of human behavior.¹⁰

(2) Another misconception centers around the problem of gradual versus sudden development. The belief in gradual development and the belief in qualitatively different stages are not necessarily mutually exclusive. A stage may be characterized by the predominance and frequency of forms of behavior "critical" for that stage. One might, therefore, reasonably expect a good deal of overlapping of lower and higher forms of behavior. This is particularly true when calculations are derived from a great many subjects. Thus, with respect to frequency of dominant characteristics the concept of

gradual development may be applied to qualitative stages; but this does not mean that it necessarily pertains to processual changes. There are some, who still believe trial and error to be the prototype of problem solving behavior; they are opposed by those who, like the Gestaltists, find the essence of reasoning in sudden, insightful reorganization. Experiments by Harter, Roberts, Jones seem to suggest that trial and error behavior is the more frequent the more artificial the relationships are that have to be detected (69, 154, 92, 59). In truly meaningful situations suddenness of part or whole solutions seem to be the rule rather than the exception (Alpert, Kreezer and Dallenbach, Hazlitt; 2, 103, 70).

(3) Much controversy stems from a confusion of the concept of qualitative differences with that of innate differences. It has been argued, for instance, that children reason in a primitive way only because they lack the fund of knowledge that education later on provides. This argument is irrelevant as to the problem of qualitative levels; it refers solely to the relation of maturation to training. With few exceptions little effort has been put forward toward an analysis of this relationship. One comprehensive experiment, conducted by Williams under the direction of the writer, has been concerned with the influence of experience upon children's concepts of causal relations (187). Children six to ten years of age were first requested to explain simple physical experiments, such as the rise of water level due to the immersion of an object. Later on they were provided with some experiences related to single factors that were involved in the demonstrated event. Afterwards the first experiment was repeated. The results indicate that certain experiences were capable of lifting the children's causal concepts to a higher level. But the results also show that there are limitations to this advancement corresponding with the child's state of intellectual maturity.

(4) Other arguments concern the relation between reasoning stages and chronological age: Piaget's and other writers insistence on a definite relationship between levels of reasoning and chronological age have brought about undue criticism of the concept of thinking stages *per se*. The criticism is justified in so far as the levels of reasoning cannot be considered to be a matter of chronological (or mental) age

alone. They depend, to a large extent, on the nature of the task at hand, its difficulty and familiarity; they also depend on the child's psychological environment and on his training. We may, therefore, not be able to identify stages of reasoning in terms of mean chronological ages. We may, however, quite reasonably, direct our effort toward the analysis of developmental sequences of thought that are less strictly related to chronological age. It has been generally found, for instance, that Piaget's subjects, coming, as they do, from poor homes, were retarded in concept formation when compared with children employed by us and other investigators. We also found that, with respect to explanations of—psychologically—remote phenomena, such as clouds, lightning, rain, etc., children remained for a longer time on a primitive, ego- and anthropomorphic level than with respect to interpretations of common technical events. Norman Maier found that creative synthesis of two learned experiences, considered by him as the essence of reasoning, was not operating before five to six years of age. However, it must be conceded that the genetic appearance of reasoning most probably depends on the type of task involved. A good illustration is afforded by K. Buehler, Alpert, Richardson, a.o. (28, 2, 152). For instance, a piece of biscuit was placed slightly out of the infant's reach, with a string attached to it. A child, one year of age, in general, is able to secure the biscuit by using the string. Before that age string and biscuit obviously are two different experiences for the child. One may therefore assume that the ability to synthesize and to reorganize two experiences into one novel action develops earlier in a simple sensory-motor situation than it does in a situation like that of Maier in which rather complex space relationships are involved.

In concluding this discussion, one might predict that the controversy concerning genetic stages of reasoning will finally be decided through longitudinal studies based on individual experimental analysis.

7. Speech

Considering the importance of speech for human behavior, surprisingly little has been contributed by genetic experimental psychologists to our understanding of the development of language. Most of the valuable contributions come from systematic observations, not strictly

experimental in nature (C. and W. Stern, K. Buehler, Bean, Nice, Markey, Lorimer, Guillaume, a.o.; 169, 28, 17, 136, 119, 111, 66).¹¹

Three aspects of language will be briefly discussed: (a) the aspect of external form; (b) the semantic aspect; (c) the functional aspect.

Probably most thoroughly studied is the development of *external form*. Differentiation of sentences as well as words out of "holophrases" (one-word-sentences), the increase of syntactic over paratactic sentence structure, the differentiation of word categories, etc., were analyzed by McCarthy, Fisher, Smith, a.o. (112, 51, 165, 166).

Few experimenters, mainly French (Decroly, Guillaume) and Russian (Vigotsky), have studied *semantic* development (42, 66, 176). In this country, a promising technique was developed by Scott and Myers: children of the fifth to the eighth grade had to interpret a number of concepts from history and politics. One of the interesting results of this study is that words were often used correctly without knowledge of the correct meaning (157).

The *functional* aspect of language is manifold. One of the functions of language is *representation*, or *symbolization*. Modern neuropsychologists, such as Head, on the strength of their clinical evidence, are inclined to consider symbolization as the essence of linguistic function (71). During early stages speech and gesture are molded into one undifferentiated form of expressive behavior (Nice, 136).

Naming as the central process of representation undergoes a development that we previously attempted to outline by the following hypothetical schema (180):

- (a) the name as a material property of a thing (dynamic "word realism")
- (b) the name as a concrete physiognomic picture of a thing (concrete word dynamics)
- (c) the name as a physiognomic diagram of the concept (abstract word dynamics)
- (d) the name as an algebraic-like sign of the concept (abstract word algebraism)

Another important language function consists in *communication*. The development of the communicative function is closely related to the social and individual development of the child. As will be discussed later, during growth the polarity between the person and his social

world increases. These processes of individuation and socialization advancing steadily with the growing child are faithfully reflected in the speech area. Language starts as a predominantly egocentric phenomenon that differentiates in two directions: there is an increase in the communication with others; socialization; but there is also an increase in the communication with oneself: inner speech development.

Experiments on *linguistic socialization* were instigated particularly by Piaget (141). Originally, the child's speech does not fully take into account other persons as listeners. The older the child, the more he becomes motivated to formulate his ideas in regard to the listening person. A tremendous decrease in egocentric speech seems to occur between three and seven years of age. Percentages of egocentricity reported for early childhood range all the way from 60 (Piaget) to 4 (McCarthy). The study by Smith corresponds closely with the results of our own investigations. We found a decrease of egocentric speech from 40 per cent at the two-year level to 20 per cent at the four to five year level (141, 112, 166, 180). Experiments on the development of *inner speech* were initiated mainly by Vigotsky (176). He found that, compared with the true inner speech of the adult, egocentric speech of young children has a higher social connotation: if these children were brought together with deaf and dumb children, egocentric speech decreased. As the person grows older, egocentric speech becomes more and more the medium through which the person communicates with himself and clarifies his own ideas. With the exception of Vigotsky's work, this writer does not know of any attempt devoted to the genetic analysis of the process of internalization of language.

8. Personal and Social Development¹²

Growth of individual personality and social development are interdependent processes. This interdependent development can be defined as growing differentiation, or polarity, between the person and his social world.

Ego and world are maximally fused in early infancy. As the child grows, he increasingly differentiates himself, in experience and in action, from his surroundings; reciprocally, the social world with which he communicates unfolds in its specificity and complexity.

Socialization. The young child's empathic

identification with his personal surroundings, its growth toward an articulate ego-world relationship have been beautifully demonstrated in L. B. Murphy's experimental analyses (132). A good illustration of the highly egomorphic world of the young child is seen in the frequent occurrence of the imaginary playmate, the self-dramatization in play situations, and the like (18, 118).

The changing relationship between the growing person and its world is usually preceded by periods of crises, of which three have been particularly pointed out by child psychologists. These are the periods of weaning, the resistance period, and the negative phase of puberty. Experimentally best documented is the resistance period, particularly through the work by Caille and Reynolds (30, 180, p. 453). The genetic significance of the resistance period does not solely lie in the growing assertion of the self, as often has been said. This period plays a singular rôle in the process of socialization; it is relevant to the genesis of *moral-social attitudes*, such as *obedience*, sense of *duty*, etc., that, according to Piaget, Buehler, a.o., develop during the preschool years (144, 27). This is clearly indicated in an interesting study by Klein (101). Klein observed a change of process patterns underlying the development of the attitude of obedience. Before a noticeable rise of resistant behavior, that is, during the first year, obedience is "blind"; it occurs in terms of simple stimulus-response reactions. Later on, during the second and third year, the child becomes inclined to "give in" only after deliberation; this change shows itself objectively in an increase of the frequency of hesitation and protests before obeying. During the elementary school years, the obedience pattern undergoes a new change. McGrawth questioned children of preschool and of elementary school ages and found that most of the four-year-olds, but only half of the seven-year-old children, appreciated the necessity of the act of obedience (23, p. 45).

Child behavior primarily controlled by strict obedience points to a comparative lack of differentiation between ego and personal surroundings. Thus the just mentioned changes of obedience patterns signify a developmental increase in the polarity between the individual and its social world. Piaget analyzed this development, particularly during the later school years, by means of most ingenious experimental

devices (144). He studied the social attitudes of children united in a "society" of their own; the children were members of groups who played a traditional Swiss game, the marble game. According to Piaget, egocentric forms of social relationship, authoritarian in nature, undergo a fundamental transformation at about the ten-year level. Before that age level is reached the "law" of the society, i.e., the rules of the game, is thought of representing an authority, superseding the will and desire of any member. In later years the authoritarian law becomes the "law of the people"; it is the free pronouncement of the mind of the individual as a member of the group. Some findings by H. Hetzer seem to support Piaget's conclusions (74). Hetzer, observing children's games in the streets of Vienna, found that up to ten years social games were preferred which are built on rigid and very specific rules; older children favored games with rules general enough to leave greater freedom of action. Piaget discovered a similar development pertaining to moral ideas, such as justice. He defined three stages: justice based on authority, on equalitarianism, and on equity. Since these levels depend greatly on cultural determinants, the chronological ages corresponding with these stages probably are not as fixed as Piaget seems to assume. Harrower, for instance, was able to confirm these stages for children of lower but not of higher socio-economic status (68).

Individuation. Another significant trend concerns the increasing appreciation of oneself and other persons as discrete and unique individualities. A number of experiments dealt with the genetic change from an egocentric level of self-esteem and evaluation of others, found in young children, to a more objective attitude of older children.

Greenberg's experiments indicate that objective appreciation of others in a competitive situation is unfrequent before the eighth year (65). Again, younger children expect good school reports independent of their actual achievement. According to Buehler, an objective attitude toward oneself cannot be expected before the nine-year level; from nine to thirteen years, school reports were increasingly more often judged in terms of "fairness" of the teacher (27). The reason for this change seems to be related to another genetic trend: the younger child judges himself and others mainly in terms

of concrete conduct; the older child becomes more and more aware of inner motives and enduring personal capacities. This development has been excellently demonstrated by Piaget (144). His experiments have shown that the idea of guilt, first related to the physical effects of a person's action, changes to a concept of responsibility based on inner motivation. The development toward "internalization" of personality traits can be inferred also from the well-known findings by Clem and Smith (33). Their results indicate that, during high school years, the attitude of children with respect to habits, such as swearing and drinking, becomes gradually more tolerant, whereas the attitude toward character traits such as conceit and selfishness, grows less tolerant.

The older the child grows the more complex becomes his personality structure in terms of differentiation of specific traits and regions of activity exhibiting those traits. It is of course impossible to list all the principal experimental results of this development. Only one more significant trend may be mentioned; viz., that toward consolidation, or stabilization, of traits and of growing flexibility. A good illustration of this tendency is furnished by a study by Schuler (156). Schuler, employing adolescent boys as subjects, found an increasing differentiation of behavior as to dominant and submissive characteristics. For older boys there is a greater stability of basic-dominant or submissive-behavior patterns within a general environment, but at the same time it becomes less possible to predict such tendencies in another general environment.

In conclusion: socialization and individuation are but two aspects of the same polar development. Higher forms of integration appear, as H. H. Anderson has shown in his significant studies, when the individual spontaneously and flexibly responds to differences in other persons (4). Dominant behavior, for instance, is in its pure form egocentric and rigid; domineering leadership is genetically inferior to leadership in terms of highly integrated, plastic behavior. According to Pigor's investigations, this latter form of leadership does not make its appearance, in general, before the age of nine or ten (145).

Primary Development of Group Behavior. Much experimental evidence supports the theoretical supposition that groups and group be-

havior develop in terms of differentiation and hierarchic integration.

A number of studies have been concerned with the increase of social activity and with the decrease of solitary play during early growth (21, 74, 110). We may, in particular, discuss briefly the results of experiments on the development of groups with reference to complexity, articulateness, and stability of organization.

Complexity. The number of group members increase with advancing age. In general, during the first year of life, direct social contacts are limited to two individuals at a time. Not before he reaches school age will the child, in general, spontaneously participate in the activity of a well-defined group composed of more than three members (27, 189, 138).

Articulation. Primary relationship between group members is egocentric, the interaction between them rather loose. The homogeneous, vaguely integrated character of primordial groups has been well observed in the "parallel" play of children. A higher step has been determined by Parten and Newhall as "associative" play; here the group is united by a common activity, such as road-building, but the structure is still ill-defined and division of labor lacking. Better articulated groups develop in the "co-operative" play. In cooperative play there is division of labor, group censorship, centralization of control, and subordination of the individual aspiration to that of the group. Parten and Newhall found clear evidence of a relation between age and degree of group organization (138). One cannot, however, accept these genetic relationships as dependent on age in an absolute manner: genetic steps of this sort are apt to repeat themselves whenever the child meets with a novel, more complex situation. This is well illustrated by the development of group behavior at the elementary school level, as studied by Reininger (148). The beginners' class as a whole displays, at first, a low form of group structure that possesses all the characteristics of a crowd. Organization grows through the initial forming of a few isolated nuclei. The nuclei are small units, each having its leader. Further organization develops by the merging of the enlarged nuclei and by the differentiation of the rôles assumed by the group members.

Stability. Many observers in genetic social psychology have commented on the developmental

trend toward stabilization, duration and definiteness, of groups and relations within the groups. Russian psychologists have shown that during Kindergarten age groups exist only for a very short time. Only one third of the groups observed remained intact for longer than 20 minutes. During school years groups grow in endurance; however, larger groups are less stable than smaller ones. In general, it is not before the age of eight to ten years, that relatively larger groups—such as boys' gangs and girls' club—begin to form (47, 190).

Definiteness of group relations have been measured in terms of consistency of the bond between group members. Moreno, by means of his sociometric technique, demonstrated the relation that exists between age and the degree of certainty with which a child chooses another child as a preferred partner (127).

The beginnings of the development of a rank order in terms of superiority and inferiority, of relations of equality and rivalry have been observed in children as young as eight months old. Development of stabilization of rank order relationships between members of larger groups has been studied by Reininger (147). Here again, as in other aspects of social development, the ten-year level seems to be the age mark of important changes. Before ten, these social relationships are vague and fluid; afterwards, rank order becomes increasingly more definite and stable.

GENIUS.—The term "genius" is used in two closely related, but somewhat different, technical senses in contemporary psychology. In the first sense, as popularized by Terman, it refers to any individual having high intellectual ability as measured by an intelligence quotient of over 140. Some writers refer to an intelligence quotient in the vicinity of 140 as being "near genius," reserving the term ("genius" for intelligence quotients over this amount. Others feel that an intelligence quotient of as much as 180 is the point where the term genius begins to apply. Used in this sense, genius simply means high intellectual ability, varying in the sense of being a strictly normal deviation from the average on the plus side. Although still current in this usage, and still sometimes used coterminously with the concepts of "precocious" and "prodigy," there has recently been the tendency to refer to such individuals as "gifted" because of the highly evaluative connotation suggested by the words "precocious," "prodigy," and "genius."

Some writers also include in the term genius individuals with special aptitudes independent of the findings in terms of the generalized intelligence quotient. Genius as used in any of these senses belongs to the particular field of differential psychometrics.

Genius is also used in psychology as in the more popular meaning to refer to unique achievement in some form of the arts or sciences. The technical usage roughly corresponds to the popular usage here in supposing that, although genius is based on high abilities or talents, the term should refer to attainment rather than to potentiality. Many students have shown that there is undoubtedly a very high correlation between the specific attainments of the individual genius and his intellectual abilities, but this correlation is not perfect and there are certainly cases of attainment which

amount to genius in individuals who would not arrive at any outstanding score in the standardized intelligence tests. The concept of genius based on potentiality alone then does not allow for a study of the motivational factors which turn only a relatively small number of gifted individuals into actual productive geniuses.

Earlier philosophical theories of genius, which considered the genius to be directed by a particular demon or inspiration given to the soul by God or as resultant only of favorable heredity, at the present time have no adherents. The chief findings of modern psychodynamic theory, namely that the abnormal individual varies from the normal in degree rather than kind and that abnormal mental phenomena represent simply exaggerations or perversions of the normal mental phenomena, have made it necessary for us to explain the behavior of geniuses and the productions of works of genius by the same basic conceptions that we utilize to explain normal behavior and other forms of abnormal behavior. That genius is a form of abnormal behavior is not to be taken to mean a derogatory evaluation of it. It is rather to be considered as another form of behavior following the same basic psychological mechanisms. The chief problems in describing genius are the problems of the motivation in the behavior of the genius and the choice of the products of the genius as symptoms of behavior.

Although some writers on genius consider its products to be due to superior abilities representing nothing more than positive deviation from the normal, the popular view that the genius has conflicts and that the products of genius represent the working out of his struggles has indeed something of scientific validity.

Earlier theories which looked on genius as so closely related to neurosis and psychosis that all geniuses were considered special forms of neurotic or psychotic individuals are not today widely held. It is true that genius and neurosis and psychosis all have their origins in conflicts between the basic parts of the self and environmental reality. But in the genius, these conflicts are resolved in such a way that the symptoms or products of the genius are socially useful and highly valued by society whereas the symptoms of the psychotic and neurotic are without social value and may even be antisocial. Conse-

quently, the older theories, like that of Lombroso and even the more recent ones like that of Kretschmer, are not widely held today. Lombroso definitely viewed genius as akin to insanity and as an abnormal and unbalanced deviation from the normal type. Kretschmer viewed genius as the combination of great ability with pathological tendencies invariably present. Although psychosis and neurosis are undoubtedly somewhat more frequent among individuals who are to be called geniuses, there is no evidence that they are an invariable accompaniment of genius. Since the same type of conflicts produce works of art and neurotic symptoms, it is only to be expected that artists will often be nonproductive because of personal or social reasons and hence may develop neurotic symptoms. Through his life the artist may also not be able to resolve all of the conflicts in socially productive work and consequently may always suffer neurosis.

Genius may be considered to be the combined result of superior abilities which arise largely on an hereditary basis with particularly deep psychological conflicts which serve as the motivation for the productions of the genius. Of all the modern psychological theories of motivation, psychoanalysis has given us the best insight into the nature of basic conflicts and the modes of their resolution, and consequently our understanding of genius has been greatly enriched by psychoanalytic studies. According to psychoanalysis, the productions of the genius represent sublimated, that is socially accepted, resolutions of unconscious conflicts. In their sources, the productions of genius are related to the productions or symptoms of the psychotic, the neurotic and the psychopathic character. Works of genius are similar to all of these in that there is some disbalance between the forces of the id, the ego, the super-ego and reality. Productions of the genius are socially useful and so the resulting behavior is viewed differently by society. Many geniuses are neurotic and the genius is closely related to the neurotic. In some ways the genius is even like the psychotic. The genius is, however, outstanding in one very special respect. His repressions are not severe enough to prevent his being somewhat conscious of the nature of the basic instinctual conflicts.

The basic instinctual conflicts are conflicts between the "love" and "hate" instincts. The direct expression of the basic libidinal and de-

structive urges of course does not lead to the production of genius. "I love ——" and "I hate ——" are not themselves art or science, but they are the ground from which art and science grow. These basic wishes become sublimated with a great deal of distortion in content; they become sophisticated in form; and they require a unique technical competence in production which differentiates them from normal adjustment on the one hand and from the anti-social manifestations in other forms of abnormal behavior on the other hand. These conflicts arise out of the barriers placed in the way of satisfaction of instinctual strivings by society. This is the reason why the artist and the genius are so often against society or against certain aspects of society. Although other resolutions of conflict are possible, such as repression leading to neurotic behavior or regression leading to psychotic behavior, the genius resolves his conflicts through sublimation leading to specific socially constructive behavior.

The psychoanalytic theory of motivation supposes that many conflicts are on an unconscious level and are related to the various stages of psychosexual development. The productions of the genius thus represent the working out of these conflicts through sublimation with sophistication of form, distortion of content, and with a unique competence of performance. It is easy to see how the frustration of normal erotic impulses becomes sublimated into popular love poetry and the lyrics of popular songs. It is perhaps more difficult to see how frustrations which have led to repression into the unconscious become sublimated into other forms of art, but analysis of the artist and the product is almost invariably able to show the relationship between the work of art and the conflicts of the individual artists.

According to the psychoanalytic psychologists, certain frustrations and conflict situations are universal and it should be expected that these would lead to the production of an outstanding number of important works of art. Among these conflicts are those connected with the family drama and there is a great deal of evidence that these conflicts have found their way into some of the greatest art works. That the Oedipus situation has been important in motivating great works of art is of course commonplace knowledge, the name itself being taken from the great Greek tragedy. Shakespeare's

"Hamlet," Balzac's "Pere Goriot," Stendahl's "Le Rouge et Le Noir" and Proust's "Swann's Way" are all concerned with the Oedipus situation.

The plastic arts like literature, in so far as they tell stories about people, also represent recurrently basic psychological conflicts. All the great Madonnas in the European galleries celebrate one aspect of the Oedipus situation. Landscape and still life in painting to be sure offer other problems, but popularized expressions like "mother-earth," "fatherland" and "Old Man River" give us clues to the psychological factors involved. For instance, the love of fatherland and mother-country are to be sure poetic expressions, but they are images based on very early identifications. The original environment of all of us was the mother's womb.

Analysis along the lines already given, however, does not answer the question of the particular esthetic quality in the product of the genius. The basic conflict is distorted in form because of its inacceptability in immediate personal terms to the social consciousness of the individual genius. Such distortion is similar to the distortions in dream-life and in other fantastic accomplishments. Sophistication in form represents an application of the artist's peculiar style which leads to a uniqueness in performance.

In art, the content of unconscious conflict is distorted through a sophistication of form in such a way that repressed wishes may be realized. In scientific work genius varies in only one respect from art. Sophistication occurs in terms of the elegance of theories and uniqueness of performance in the performance of experiments, but the distortion rather than leading into the field of uncontrolled fantasies represents an adaptation of wishes to reality. The scientist expresses his unconscious conflicts in a way which is true, that is which can be verified experimentally. The artist expresses in a way which is beautiful. Art consists in expressing experience in a way certain observers realize to be beautiful, while science consists of propositions to which the universal consent of other observers can be obtained. Since an elegant mathematical deduction has something of quality connected with it and a great epic poem something of truth, even this distinction is a relative one. Thus, outstanding works of science as well as those of art represent the

products of genius in that each is a socially acceptable sublimation of inherent psychological conflict.

The appeal of the product of genius to the audience is based on the fact that the audience is able to introject the distorted form of the art product or to identify himself with the protagonist and thus resolve similar conflicts of his own. Just as the artist or genius is enabled to undergo catharsis through his production, the audience likewise resolves conflicts in a sublimated form through identification.

From the modern standpoint then, genius gains understanding in its motivational aspects from the psychoanalytic study of the unconscious struggles of the genius. Genius, like all behaviors, is a function of both hereditary and environmental or psychological-field factors. The original potentiality or talent comes from heredity, but the motivation to produce comes from conflict and the type of medium also is related to the personal psychological factors which largely come from the environment. The chief mechanism of genius lies in sublimation, which is by no means the best formulated of the various psychoanalytic mechanisms, but which certainly gives us some understanding of the way in which genius works. Although a great deal remains to be understood about genius, psychoanalytic theory may be said to have made a good beginning in this field. Certainly a great deal of work remains to be done on the problems of choice of medium and the general relationship between medium or mode of expression and the nature of the underlying psychological conflicts.

GESTALT PSYCHOLOGY.—*Gestalt* psychology is one phase of a recent general trend in the science of psychology as a whole. The general trend reached a peak in its publications in the late twenties and early thirties of the century and reflected a shift in emphasis from all forms of conventional or "orthodox" psychology, which were mechanistic or "atomistic" in their pattern, to an organismic position based on fundamentally opposite assumptions.

In a brief review of this sort it would obviously be more practicable to confine the discussion to the general features of the movement and of others logically related to it, in order to bring out if possible its wider and fuller meaning. The wider movement in psychology encompassed all of its various fields and in many instances extended into borderline areas, giving rise to new branches of science. Similar movements or shifts in emphasis occurred in all of the other sciences, and in philosophy, not excluding mathematics. Not only that, but the *Gestalt* movement was only one very small part of a vast, intricate and completely integrated change in the character of the entire culture pattern of the modern, civilized world. But still this is not the whole of the general setting. The shift in the culture pattern is one which has occurred many times before in history. At certain times in history all phases of human endeavor are dominated by a pattern of thinking and action explicitly or implicitly based on "mechanistic" assumptions pertaining to the sources of truth and right—theoretical, scientific, or practical. There result typical emphases in science, in forms or styles in art, typical trends in political and economic thought and action, even typical forms and types of warfare. When the mechanistic movement has run its course, the entire culture pattern changes to an opposite set of emphases now based explicitly or implicitly on opposite basic assumptions, the organismic. Then the culture pattern shifts back again.

Space does not permit tracing these movements throughout history. Suffice it that the antecedents of the current organismic trend in psychology can be traced back to Plato and Aristotle through those periods in history that have been organismic in character while the antecedents of conventional psychology can be traced back through the alternating periods to the Hellenistic phase of Greek history. The

last two periods in the history of psychology dominated by the mechanistic pattern occurred roughly from 1710 to 1790, and 1830 to 1910, respectively. Accordingly, the last two organismic periods occurred between 1790 and 1830, and from 1910 to apparently about the present time. Prior to the twentieth century, periods of organismic thought have been vitalistic in nature, and certain of the organismic trends within this century have been vitalistic. The dates just given are valid only for purposes of orientation. It would be better to say that on or about these dates the culture pattern was in the process of shifting from one set of dominating characteristics to its opposite set. At the present moment the general over-all culture pattern appears to be shifting back again to the mechanistic phase.

What then are the general characteristics of these two patterns, the atomistic and the organismic? (There are only these two; no others have ever existed.) Fundamentally the two patterns have to do with the question: What is basic, primary, more important or fundamental in nature, and what is secondary and derived? The atomistic pattern gives the general answer that the basic or primary thing or fact in nature is an element; a particle; an infinitesimal something; an individual thing; a unit of some sort by nature self-sustaining, independent, whose properties or attributes of necessity must be inborn, innate or inherent; a cell; a sensation, an idea, a feeling, a habit, a reflex, an instinct, a government, a nation—in other words a part of something. A part, of course, implies a whole. Accordingly, the mechanistic pattern makes certain assumptions about the whole that must agree with the first assumption that the parts come first. The part or element, therefore, is used as the building brick with which to explain how, under laws of nature, the whole came into being when something or other put the parts together. The important thing to remember is that the whole is secondary and derived, something manufactured from the parts. It has no properties or attributes in its own right; essentially it does not exist except as an aggregate or mechanical combination of the parts, like a machine such as an automobile.

The organismic pattern gives the general answer that this is all wrong and professes to prove it introspectively, experimentally, and logically. It contends that not parts or elements,

but systems (of energy), patterns, wholes—the complex as opposed to the simple—are the basic, primary, and therefore the more important facts and realities of nature. The part or element is secondary and derived from the whole, by a process called individuation. In physical science, systems of positively and negatively charged particles are the basic facts; or systems of energy obeying laws of equilibrium (Neither equilibration nor disequilibration exists among aggregates or dynamically unrelated parts.) In biology the basic fact is the organism as a whole, not the cell; in psychology it is the mind or the personality as a whole, not the sensation or individual response; in social science it is a given society as a whole, such as the State, not the individual.

No brief account can possibly give the uninitiated reader a clear idea of the gulf that exists between the two patterns, or of their incompatibility, or of the utter impossibility of blending the two into one without basically altering one or the other, or both. They are logical opposites, as different as night from day; as fascistic despotism from democracy; as communism from individualism; as rationalism from empiricism; as epigenesis from preformation; as Picasso and Dali from Landseer, Gainsborough or Fragonard; as Ravel from Stephen Foster; as modern steel, glass and concrete functional architecture from 17th and 18th century Baroque and Rococo; as theism from atheism; as a systematic treatise from an encyclopedia; as international wars from civil wars. And for a very simple reason, the first named of all these comparisons belong to the generalized organismic pattern; the last named to the atomistic pattern.

In order to get parts put together into wholes the atomists must resort to mechanisms or expedients of various sorts such as bonds, attractions, repulsions, affinities, association, social contracts, or just chance, because in the beginning, by definition, the parts are not naturally related to one another, dynamically; there is in the beginning no organization, integration or interdependence. Scientific laws are supposed to pertain to the machinery by means of which the complex is obtained from the simple, the orderly sequence from unconnected events, the whole from the part, or else the laws are merely statistical. If the parts are already in an organization of some sort already

possessing form, order and dynamic relationships to each other, then they did not come first after all; the whole, with its parts already integrated in time and space was the primary fact. This is the organismic position. Hence scientific laws must pertain to the manner in which parts move or behave, or change, in already integrated systems of energy. Organismic laws pertain to the behavior of wholes, not to the process of putting parts together to make wholes, not even when the process is getting water from hydrogen and oxygen because in that process more than the two gases are involved, namely pressure, temperature, electrical, thermal and gravitational fields, along with charges and differentials in potential, all of which have quite as much to do with the manufacture of water as the gases themselves. The situation holds for any kind or form of synthesis, fusion, blending, mixing, transformation, patterning, or concatenating whatsoever.

With a few exceptions the psychological literature of the nineteenth century was mechanistic. The outstanding pattern was that of association psychology based on the mechanical laws of repetition, recency, or frequency, and the influence of pleasure and pain upon the formation of associations. This viewpoint was taken over by the conditioned response school—the behaviorists. Behaviorism and bond psychology, incidentally, were hold-overs from the 19th century, as was Titchener's structuralism—examples of cultural lag. It can be shown that during each of the mechanistic periods of history, some type of behaviorism or association psychology or its equivalent prevailed.

The first symptoms of the transition from the mechanistic to the organismic pattern were appearing during the eighties and nineties, and can, in general, be summed up as the rediscovery of *continuity*, or unity in time. The next step was the re-discovery of *unity* and its implications, i.e., unity in both space and time. Wundt's acceptance of apperception; Fechner's effort to find a systematic relationship between mind and body; James' unsuccessful but brave fight against the atomistic pattern, and his "stream of consciousness"; the British concept of conation; the concepts ideomotor action, striving, drive, subconscious, the self, and the like, belong to this period. The next step was exemplified by the work of Ehrenfels on "*Gestaltqualitäten*," and Dilthey's emphasis on psy-

chological wholes, in short, in a rapidly growing realization expressed by many authors (especially the Graz School) that psychological processes cannot be explained completely by reducing them to elements. A given mental state possessed an attribute of its own later to be designated as a "field property."

The main break took place first in Germany with Wertheimer, Köhler and Koffka, particularly with Wertheimer's work on apparent movement (1912), Köhler's experiments with apes that demonstrated transposition, insight, and goal-directed behavior as opposed to blind trial and error; and Koffka's work on perception and learning. Other investigators were at the same time breaking the old traditions. Mechanistic assumptions led to the seeking of a one to one relation between cause and effect, stimulus and response. As early as 1909 Katz found that this implication did not hold in his studies of color. Rubin further upset common notions about perception and memory in his figure-ground experiments.

The mechanists had no way of explaining how a given process such as a reflex, habit, or instinct—or for that matter, anything—got started, traveled the course it did, and finally stopped, without endowing the act with a great many mysterious, self-directing powers. As James once said, the important problem is *not* how B came to follow A the second or the tenth time, but how it happened to follow A *the first time*, before any bonds had been formed! New insight into this problem came to light in Wertheimer's famous concept of "closure," a variety of the more general principle of energy systems "seeking" stability in equilibrium.

Early in the development of Gestalt theory Köhler pointed out that the old difficulties and the new problems were by no means confined to psychology. Physical science had corresponding part-whole problems. Köhler's observations were published in 1920 in "Die Physischen Gestalten." Meanwhile, and of earlier origin, developments in physics—relativity, the quantum theory, wave mechanics, the new theory of the atom—were already breaking corresponding traditions and rapidly turning to organismic principles. In 1929 Schroedinger, a physicist, borrowed the term Gestalt from psychology (Köhler in particular).

Meanwhile, also, biology was having similar troubles, especially in embryology. The cell

theory was utterly impotent to explain the phenomena of growth. The organism consisting of billions of separate cells of different kinds was not a product of cellular multiplication at all, fundamentally. Multiplication turned out to be a *by product of division*. Division was the basic process. That meant that the whole came first even if it was a small one. This was the cue. Throughout growth the parts came from the whole, not the whole from the parts. As De Barry, a botanist, said many decades earlier, "The cells do not make the plant; the plant makes the cells." The upshot of this simple but profound reversal in thinking was a revival of earlier forms of epigenesis, teleology and all, dressed up in scientific clothes to fit the twentieth century. C. M. Child's principle of "regulation" of growth by the organism as a whole through physiological gradients; Coghill's emphasis upon individuation, a concept going back through Spencer, Coleridge, Casper Wolf, William Harvey, Duns Scotus, to Aristotle; the vitalistic assumption of "organizers" and "entelechies" (Driesch) but nevertheless a recognition that parts are conditioned by wholes, and other related concepts and trends, burst forth in biological science.

A renewed study of the causes of monstrosities that heredity could not possibly account for—transplantation of tissues from one part of the embryo to another in its earlier stages of growth; studies in symbiosis, ecology, animal and insect societies, altogether built up a tremendous organismic literature in this field. Perhaps most striking of all was D'Arcy Thompson's "On Growth and Form," first published in 1917 (second edition in 1942), one of the most scholarly, thought-provoking books of the century.

The Gestalt movement was slow to get under way in this country and at first met with bitter opposition. American psychological thought was firmly entrenched in the mechanistic pattern in three important directions as late as the second decade of the century. One was Titchener's introspective structuralism, the second was Watson's behaviorism, and the third was Thorndike's bond psychology. Actually, however, names and schools are far less important than the over-all culture pattern that prevails at the time. American thought was dominated by the mechanistic, individualistic spirit of American economic, social and political life which de

veloped throughout the nineteenth century and was fostered by a large continent to conquer. This atmosphere dominated all schools and instruction—content and methods—from the elementary grades to the graduate schools. Add to this, geographic isolation and complacency, and the stage was set for as vigorous an opposition to organismic thought in science as to socialistic trends in political economy.

Among the first to notice the new movement were George Humphry who interested himself in its applications to the learning process and education; R. M. Ogden, who translated Koffka's "Growth of the Mind"; Harry Helson, who published extensive reviews of the literature in 1925 and 1926; George Hartmann, who wrote "Gestalt Psychology" in 1935; W. D. Ellis, who wrote "A Source Book of Gestalt Psychology" in 1938; and Wheeler and Brown.

Just as modern non-Euclidian geometries hark back to Lobachevsky and others in the early part of the 19th century, and as modern epigenesis harks back to Cuvier and his followers, so modern work on the functions of the cortex hark back to Flourens of the same organismic period. The outstanding name in the twentieth century movement in this country is K. S. Lashley. The cortex functions piecemeal fashion according to the mechanistic view. A particular function like seeing or hearing is located in, *i.e.*, it "resides" in, a particular cortical area. According to Lashley's studies, this view must be radically altered, at least from its extreme form. Wheeler, Bartley, Neuman, Perkins and others insist that the cortex functions as a whole no matter what the organism is doing or to what it is responding; that there may be specialization but not localization of function; and that specialization of function is open to an explanation in terms of gradients comparable to those assumed by Child and Coghill in physiology and embryology.

Perhaps the most concentrated form of organismic psychology is found in Wheeler's "Laws of Human Nature," 1931; "The Science of Psychology," 1929, 1940; and Wheeler and Perkins, "Principles of Mental Development," 1932. After a search in the histories of the different sciences, Wheeler concluded that in a logical sense the basic laws in all were the same; that they were laws of the behavior of energy systems of whatever kind; that this was the reason why, after all, we have a Universe

(one world) and call it that; that various phenomena could not possibly be integrated with one another unless this was true; that the majority of the most important scientific contributors to science down through the centuries had always implied or stated this fact; that these principles were the basic laws of human behavior. Accordingly he boiled down the results of his historical research into a set of "Organismic Laws" with which he transposed from physics to biology to psychology, to social science, and from one division of psychological subject matter to another, in the fashion of Oswald Spengler, F. C. S. Northrop, George P. Conger, and numerous others.

Originally associated with Köhler in Berlin was Lewin, who applied the technique of topology to problems of goal-directed behavior. The individual lives and moves in a physically and socially structured field, a situation capable of being portrayed by topological figures. J. F. Brown, a follower both of Köhler and of Lewin, extended this method to a systematic social psychology, "Psychology and the Social Order," 1936, and into the field of abnormal behavior, "Psychodynamics of Abnormal Behavior," 1940, where he combined the principles of psychoanalytic theory with Gestalt psychology.

It is characteristic of organismic times to break down departmental barriers and hence to adumbrate new branches of science, although the effort sometimes results only in pseudoscience. Examples of this sort are found in the several efforts at characterology and typology, all of which were based on the assumption of the psycho-somatic unity of the individual as a whole. Kretschmer's classification of body types into pyknic (frequently associated with extroversion), asthenic (associated with introversion), and athletic (ambivalent) is an example. There are many others.

The general movement in psychology away from sensationism or any emphasis upon elements of consciousness or elements of response, to an emphasis on the personality and its adjustment, and on social behavior, followed the trend in general toward wholes. A similar reaction against "brass instrument" psychology occurred in the culture psychologies of Europe.

The movement in psychology and psychiatry toward Freud was also typical. Organismic cultures are always more subjective and introspec-

tive in character than the mechanistic, with an inclination, in occidental countries, toward eastern mysticism.

Both the organismic and mechanistic patterns pass through their brilliant phases, sinking into decline before the pattern changes to its opposite. One of the symptoms of the decadence with which organismic eras always terminate, a symptom traceable through centuries of time, is a hyper-sex consciousness associated with moral decline, nudism, lowered physical vitality and a decline in the birth rate. Whether or not the student of modern society would admit that we have passed through a period of decadence in the last twenty-five years, the fact remains that the civilized world became hyper-sex conscious, along with waves of public necking, nudism, increased promiscuity, and a decline in the birthrate. This is obviously one reason for the great popularity of Freud and psychoanalysis. Similar trends in medicine, even to the same emphasis upon dream analysis, symbolism, the subconscious, and sex can be found during decadent phases of the various organismic eras as far back as the periods of decline in Rome and Greece. Declines in the birthrate also occurred during these periods. The conclusion is inescapable that the decadence is to a considerable extent due to lowered vitality and that the undue emphasis on sex is an effort to compensate for that lack. When the race is the strongest it seems to be more puritanic, and less sex conscious; when it is the weakest, it seems to be less stable, less puritanic, and more sex conscious. Be this all as it may, the emphasis in psychoanalysis upon the personality as a whole and its struggle for internal balance is definitely a move in the direction of the organismic pattern. Neuropsychiatry, also, was not without its strong organismic representatives as in the case of Goldstein whose point of view is found in his book, *The Organism*, 1938.

As time went on the structuralists, behaviorists and bond psychologists became less extreme, less skeptical, and in many cases adopted ideas from the organismic movement, *i.e.*, they more or less joined, later, the trend of the period that was historically "on time." Tolman's emphasis on goal-directed behavior, Hull's hypothetical-deductive approach, and Thorndike's adoption of "belongingness" are cases in point. There are others too numerous to mention.

Education shifted from a rigid departmental-

ized system based on drill, bond psychology, and hedonism to liberalized curricula and methods intended to provide integrated experience and to develop integrated personalities; thus, education strongly participated in the movement as a whole. Special orientation and survey courses were provided, and an effort was made to make schools "student centered." The purpose of education became to develop insight and the comprehension of things in relation—wholes.

Logic and philosophy were not immune to the general change in the thought pattern. Induction, empiricism, materialism, pluralism, hedonism, all gave way again to rationalism, neo-Platonism, idealism, monism, an interest in methodology and the logic of science, and in broad, sweeping, universal principles—in short to a philosophical presentation of the part-whole problem with the use of organismic principles (Bradley, Bosanquet, Bergson, Whitehead, Northrop, Reiser, the "Viennese Circle," Conger, *et al.*). A new journal, "The Philosophy of Science," was motivated by this change.

Space forbids giving an account of similar movements that took place in the social sciences: sociology, economics, political science, and history. Suffice it that the trend was associated with an emphasis upon the reality of the State or large social group, treated as an integrated whole, a natural object of a kind in its own right, as opposed to an aggregate of interacting individuals. In practice the result was a turn to the left or to fascism in both of which the social part, the individual, was subordinated to the social whole, the State. During mechanistic times the State is subordinated to the individual and during organismic times the individual is subordinated to the State, hence a high correlation exists through history between mechanistic cultures and the growth of individualism and democracy, on the one hand, and on the other, between organismic cultures and the rise of absolute monarchs, or totalitarianism in any one of a great variety of forms, including communism. The socialistic writings of the past, as of the present, generally belong to the same culture pattern.

A very interesting development in organismic science of which psychology is yet hardly conscious, but in which it is definitely involved, is that of human ecology. Included in this movement is a rising interest in the effect of weather

and climate upon human health, vitality and behavior.¹

The mathematician has often said: One does not really understand algebra until he has struggled through the intricacies of higher, abstract mathematics. Truly it is not possible fully to comprehend the significance of the early contributions, in Gestalt psychology, of Wertheimer, Köhler and Koffka, until one has laboriously studied the corresponding trends not only in all of the other sciences, but in the world of human action as well in the past where history has been made, and in the present where history is in the making.

H

HYPNOANALYSIS. — As with almost everything else, it has transpired that the psychotherapeutic wheel has come about full circle. Techniques which were hastily although somewhat regretfully abandoned in the past are now believed to have some value, and there is evident a general movement pointed toward the re-evaluation of clinical procedures and tools. Under the stimulus of the war, and faced by the dire prospect of a virtually endless stream of psychological casualties not only from the front but from the homelands as well, it has become important to sift our knowledge in the hope of finding handy tools with which to operate. At the same time, this is not to imply that the methods and instruments to which we of science return are the same antiques we abandoned in the forward flight. Rather it would appear that the inevitable march of time has supplied us with the knowledge to utilize them in a more serviceable and expert manner, to which the special insights of the laboratory and praxis have contributed. It should further be remarked that there is a visible boldness in our manner now that was heretofore lacking, and that it is perhaps just this quality by itself which accounts for the success that meets current psychotherapeutic efforts. No longer is investigative and therapeutic procedure devious and subtle. We have come to the age of heroics in the application of knowledge. With the organism becoming more familiar to us and more knowledgeable through technical advancement, we can and do attack it frontally.

Hypnoanalysis is a radically abbreviated form of deep psychotherapy which takes its departure from psychoanalysis but which, at least to the moment of this writing, confirms rather than disputes the findings of the more orthodox analytical approach. Its roots are in a past that is heavy with tragic history. While the technique in itself, as it has grown under the careful and inquiring hands of latter-day investigators, is approaching methodological formulation and

theoretical maturity, it is still in process of growth. To be able to view it in proper perspective and to weigh its potentialities, something of its antecedents must be surveyed.

As an adjuvant to therapy, hypnosis has commanded the attention if not the respect of the biological arts and sciences since past ages. It was known to and practiced by Babylonian soothsayers, Egyptian wizards, Hebrew physicians, and more than likely the predecessors of these as well. As the philosophical and religious preferences of its practitioners differ from place to place and time to time, so did the various views of its nature and functions alter. At times it was regarded as a unique and special attribute of particular persons, a divinely-granted and sanctioned power or gift; at other times it was held to be an instrument of dark powers and a force for evil. It is impossible to date the awakening of scientific interest in hypnosis, although the literature suggests alchemical concern with it during the so-called middle ages. At any rate, a resurgence of popular interest came in the middle and late 18th century with the widespread application of "animal-magnetism" for curative purposes by the flamboyant Mesmer. This extravagant personality forced attention to the phenomenon, and were it not for his personal noxiousness and his great talent for alienating his colleagues by his excesses, it might have taken its place among respectable methods of treatment. Instead, by virtual decree of the French Academy of Sciences, it was banished and proscribed. Utilized in secret only by the more rash and radical spirits, it came to be regarded more as a device for entertainment and mystification, and for many years its therapeutic possibilities were neglected. Most psychologists are familiar with the recent citation of hypnosis as an aid to therapy in the latter part of the 19th century, and know the fascinating story of its recall from limbo by James Braid, the struggle between Charcot and his physicalists of the Salpêtrière and Liebault and

Bernheim of the Nancy suggestionists. Suffice to recall that, in general, the basic propositions of the Nancy group prevailed and that Freud, who although he was a student of Charcot, incorporated this view into his early therapeutic work.

The abandonment of hypnosis in deep therapy by Freud and his followers had unfortunate consequences for the development of an instrument of treatment which was later to become hypnoanalysis. It again permitted hypnosis to sink into a tradition of disrepute; but more important, it prejudiced against it the very workers whom it needed for its theoretical and practical development. The psychoanalysts were possessed of a comprehensive and dynamic psychopathological framework for it, but they summarily dismissed it from their total referential pattern, except for (curiously enough) Freud himself—who devoted considerable study to hypnosis and even centralized it in his work in group psychology—and, later, E. Simmel. That it retained its attractiveness, however, is testified by the concern it commanded during and after the First World War and through the years to the present by such analysts and analytically oriented investigators as Anna Freud, Ferenczi, Jones, Schilder and many others. It seems, somehow, that in spite of the orthodox injunction against it, the potential utility of hypnosis in explorative and depth psychotherapy was recognized.

Hypnotherapy, as Brenman and Gill have demonstrated in their brilliantly executed monograph, is a generic term covering the application of hypnosis in psychotherapeutics. These authors make out six ways in which this is done. They are: (1) Prolonged hypnosis without direct suggestion or exploration; (2) Direct suggestion of symptom-disappearance; (3) Direct suggestion of disappearance of attitudes underlying symptoms; (4) Abreaction of traumatic experience; (5) The use of specialized hypnotic techniques; and (6) Hypnoanalysis. It is with the latter that we shall here be concerned.

Hypnoanalysis is a term properly reserved for those therapeutic efforts in which hypnosis is combined with the techniques of psychoanalysis in service of the goals of treatment. That is to say, the propositions basic to hypnoanalysis are derived from dynamic depth psychology, and the methodological approach incorporates hypnosis. The exact ingredients of this combination

depend upon the variant of hypnoanalysis employed. The one which will concern us here is the variant this writer has shared in developing, but the aims of all forms of hypnoanalysis are similar. They are: (a) to seek out the hidden pathogenic agents; (b) to realize an abreaction in which the total personality shares; and (c) to more hygienically redistribute the energies formerly exploited by the pathological processes.

In the variant of hypnoanalysis with which the author is best acquainted, intensive training in hypnosis marks the opening phase of treatment. Patients are instructed in hypnosis, their misconceptions regarding it are dispelled, they are literally *taught* how to be hypnotized. Alternate methods for the induction of the trance state are utilized, depending upon the peculiar problem brought to analysis, the special character of the patient, and his condition. A general rule is that which bids the clinician to exploit existing physiological trends which are apparent to him from his clinical intuition and experience. The extent of the period of training is approximately one week. During the daily session, the special problem or perplexity which encouraged the patient to seek help is not discussed. At the end of this initial period, the patient should possess three capabilities which are necessary to the progress of the analysis: he should be able to enter the trance state immediately upon the suggestion of the hypnoanalyst; he should be able to carry out post-hypnotic suggestions with ease and rapidity; he should be able to revert memorially to former scenes and places. This latter capability presents a delicate problem, calling for the exercise of considerable care. The clinician must encourage two varieties of memorial reversion: the *regressive*—where the patient recalls previous experiences but views them in the light of his present outlook—and the *revivified*—where the patient actually relives the event by returning to the previous biographical setting and literally participating in it once more.

The second phase of therapy utilizes the method of free-association. The patient is directed to choose a starting point and to associate without regard to form or content. The usual psychoanalytic principles are followed as hour succeeds hour. When resistances are encountered, however, free-association is abandoned for hypnotic recall. Resistances are not analyzed, but rather undercut. The patient is hypnotized and

urged to reveal the nature of the matter to which he has demonstrated reluctance. If the matter is biographical, either regression or revivification may be employed, although it appears preferable to call upon the former in early phases of treatment and the latter later on. The so-called *interim phenomenon* enters at this point. Research has revealed that an unvarying sequence of events transpire when hypnotic recall is performed in the course of an hypnoanalysis: (1) resistance to free-association is present; (2) the patient recounts or reenacts the crucial material, be it event or phantasy; (3) soon thereafter the same material to which resistance had formerly been shown, if it is memorially valid, appears in the waking state in free-association. What apparently takes place to account for this important phenomenon is that the process of revelation under hypnosis exerts an effect upon the conscious ego, readying it in the interim for the often uncomfortable and unwelcome disclosures which have been made already under trance conditions. This single feature of hypnoanalysis makes the analysis of resistances superfluous, and permits the clinician to come to grips with crucial matters affecting the patient.

Now as the repressed and deflected come to light both in the waking state and in the trance, the therapist can validate the contents of the analysis, can fill in the gaps, and manipulate the analysis so that he is assured of the import and scope of each item. This he can do, if it is necessary, by viewing the material in both situations, and so obtaining a better and well-rounded picture of the problem at hand. He can and must also assure that the entire personality shares in the abreactive process. It is a cardinal principle of hypnoanalysis that abreaction take place in the waking state so that the entire functioning organism will share in the established therapeutic benefit of this process. Under regression and revivification there will appear crucial and dramatic events of biography which are of pathogenic significance. Until the fully integrated organism participates in these, hope of success in therapy is forlorn. As a matter of fact, unless this is accomplished, the essence of hypnoanalysis is lost, and all the negative criticisms which apply to the superficial suggestive therapies will be in order.

Yet another feature of technique for the middle phase must be mentioned. It has been found

that often the waking organism is unprepared for the acceptance of material which has been revealed under hypnosis. Because of this, it becomes necessary to follow each episode of trance with post-hypnotic amnesia for the contents of the trance, thus permitting the interim phenomenon to accomplish the ego-preparing work of paving the way for a routine acceptance of such items.

The final phase of therapy is entered upon when it becomes clear that all the factors accounting for the therapeutic problem have been exposed, reacted to, and examined. The transference relationship which has, during the hypnoanalysis to this point, been exploited for continuity of treatment, now becomes the central agent for bringing it to a close. In essence, this final phase is synthesizing and educational. From the exploration of the total organism there will have appeared varied pathology of ideas, goals, and attitudes which have originated in misconceptions, misinterpretations, and from the employment of the various mechanisms of defense. The hypnoanalyst now has as his task to reeducate his patient in respect of all of this, and to exert toward the reorientation of the personality along more hygienic lines. Herein the usual techniques of psychoanalysis are employed, but these are re-inforced by post-hypnotic suggestion. More than mere verbal acceptance of the new goals, attitudes, style of life, ways of regarding the past are required by hypnoanalysis. These must literally be incorporated into the performing organism and be shared by it in all the levels and segments of the personality. What is called for is a real engrafting process. At last, the transference relationship is dissolved. This is accomplished by redistributing its energies along the lines indicated by the therapeutic course. Here, again, hypnosis is drawn upon as an agent of enforcement to exert an effect upon those components of the organism not otherwise accessible.

The problem of the operationally effective field for hypnoanalysis has been under examination by this investigator and others during the past few years. At the present writing, it appears that the technique is applicable in every instance where a dynamic investigation of the personality is wanted, and to the treatment of such psychogenic disorders and aberrations in which there is presented to therapy a relatively intact ego. The limitation regarding the intact ego

may possibly not hold; yet the present writer has encountered serious difficulties where this caution has been violated, and believes the matter is still in a research stage. The categories to which hypnoanalysis has been applied with success by the author and others are as follows: hysterical somnambulism, anxiety neurosis, homosexuality, alcoholism, kleptomania, schizoid personality, symptomatic asthma, frigidity, adult maladjustment, conversion hysteria, psychopathic personality, problems in adaptation, and pre-psychotic personality types. To this list, workers at the Menninger Clinic add anxiety hysteria, hysterical psychosis, neurotic depression, and psychogenic reaction to pregnancy.

Hypnoanalysis has many advantages. It is rapid and effective, and appears to be widely applicable. On the other hand, it requires a high degree of training in the clinicians who employ it, calling for a basic knowledge of psychodynamics, psychopathology, and psychotherapy. Furthermore, it makes special demands upon the therapist due to the peculiar inter-personal relationship that obtains between hypnoanalyst and patient. This relationship transcends even the close transference situation obtaining in psychoanalysis. The setting of the treatment provides, at times, a prone, pliable, and trusting subject who can be used by the therapist as an object and target for his own frustrations and hostilities. It demands, therefore, that the therapist have himself well in hand if he is to operate with the requisite scientific circumspection as an hypnoanalyst.

There is no question but that hypnoanalysis offers a fertile therapeutic and research field. It is the youngest of psychotherapeutic forms, and on the basis of performance to this date seems promising. In summary, it is a method which, to quote a previous report of this writer, "aligns itself with psychoanalysis as a form of therapy

which aims at routing out from the deeper levels of the personality the specific agents responsible for the observable pathology. It operates to expose the basal mechanisms and processes on which depends the pathological process clinically visible or at least reportable as aberrative behavior, psychogenic disorder and malfunctioning, and maladjustment. Under its methodological terms, it circumvents or disposes of the objections classically leveled against the use of hypnosis in therapy. It guarantees the participation in abreaction of the total personality; it deals with the basic sources of conflict rather than symptoms; it exploits the transference relationship; it establishes therapeutic controls and safeguards; and it enables continued validation of analytical material. . . . It is a radically abbreviated form of dynamic psychotherapy, the operational field of which has been defined as (at present) extending to cases wherein a relatively intact ego is presented to therapy. The method makes special demands upon the clinician, relating to his observance of certain operational rules and to his self-knowledge. It is, in short, another weapon in our relentless and unremitting fight to free mankind from those ills and perplexities which blight his existence and shorten his days."

INDIVIDUAL DIFFERENCES. — That differences exist among human beings has long been recognized, but not until people were subjected to quantitative measurement was the fact experimentally established that every individual is unique. While most characteristics are common to all people, each person has a different degree and a different combination of these characteristics. Individuals differ widely in physique and general appearance; in all their abilities, whether general intelligence or special aptitudes, such as motor ability, music and art; in their interests and desires, their moral standards, and in their ability to withstand thwarting of their emotions.

Marked individual differences are as common in infra-human as in the human species. Experimental studies of monkeys, apes, rats, and guinea pigs, have indicated wide variation within each species in learning and problem solving ability, in social domination and in neurotic behavior. Pronounced variations in structure and function have been found within all levels of organisms throughout the phylogenetic scale. Among animals of different species variation in the rate of learning is more definite than among different animals within any given species because of the wide diversity in neural and bodily structure. Variations in temperament and in physical structure also affect the performance of any animal. Differences in capacity for education and vocational success are dependent upon such variations.

Definitions of intelligence and other aspects of personality differ, and there are difficulties inherent in the tests and other measuring instruments used, nevertheless, knowledge of human variability has steadily increased in range, detail, and accuracy. Standardized tests and other techniques now provide fairly reliable methods for determining the kind and degree of individual variation in many traits. These techniques which psychologists have devised have shown that no two people are alike in any traits studied. Ability to understand human be-

havior rests largely upon recognition and understanding of individual differences.

Historical Background. Through keen observation and logical techniques, the ancient Greek philosophers accumulated facts on human variation. Clear evidence of the early recognition of such differences may be found in the Republic of Plato. He states: "No two persons are born exactly alike, but each differs from each in natural endowments, one being suited for one occupation and another for another." Plato believed every individual should perform those tasks for which he is best qualified by nature, whether labor, business, the army, or the administration and government of the state. He advocated little training for the laboring groups because they were poorly endowed and did not warrant the expenditure. For the mentally superior, on the other hand, he advocated prolonged and intensive intellectual training to prepare them as rulers of the state.

Aristotle, too, recognized that individual differences exist, but he devoted far less space in his writings to a discussion of human variations. In contrast to Plato's hereditary caste system of education, Aristotle stressed the differential effects of education on individuals of varying abilities. He stated that the possibilities of change within a given person are limited. He recognized clearly that some persons have superior endowments while others may be handicapped at birth.

Throughout the Middle Ages, individual differences were largely ignored, since institutional Christianity placed its emphasis on spiritual equality. This almost complete neglect of human variations continued through the eighteenth and into the nineteenth century, until Rousseau, Pestalozzi, Herbart, and Froebel pleaded for recognition of the educational needs of the individual child.

Up to and throughout most of the nineteenth century, all principles of human variability were derived from crude observation alone. Until that time, no techniques for systematic and experi-

mental studies of individuals had been developed. The earliest systematic measurements of individual variation were made by astronomers who compiled records of observers, noting differences in the estimates of two or more observers and also in any given observer from time to time. Such studies came to be known as measures of the "personal equation" of different individuals. However, the study of individual differences really grew out of experimentation which had for its aim the discovery of general principles concerning human behavior. Many of the personal variations which occurred in the early stages of this experimental work were ignored or regarded as errors. As the experimentation progressed psychologists recognized that these variations were real and were deserving of special study.

The pioneer in extensive systematic and statistical investigations of individual and group differences was Sir Francis Galton, who initiated the "eugenics" movement, and who more than anyone else may be considered the founder of the science of individual differences. He stimulated interest in many studies in the field of human variation, and devised tests for the measurement of differences in discrimination of weight and auditory acuity. He also developed statistical techniques for the analysis of such data, and studied aspects of personality, such as character, by empirical methods. As early as 1884, he established a laboratory wherein mental and physical tests—largely sensory and motor—could be taken for a small fee. He was a pioneer in the use of the rating scale and questionnaire methods widely used today in studying personality differences.

Inspired by the work of Galton James McKeen Cattell and Joseph Jastrow in America devised tests for measuring the relatively simple sensory, motor and perceptual abilities. These tests were used with a large number of subjects over a period of many years, and the results compiled and analyzed statistically. From the outset of his career Cattell was impressed with the variability of human performance, and the need for prolonged and careful observations in order to arrive at reliable results. He was one of the earliest psychologists to introduce quantitative methods for the measurement of individual differences.

The trend of the growing movement was changed by Alfred Binet, the great French psy-

chologist. He stressed the importance of measuring the complex, higher mental processes rather than simple sensory and motor abilities, since differences are more marked in the former. Binet realized that the higher mental processes could not be measured as precisely as the simpler sensory-motor abilities, yet he was willing to sacrifice the greater degree of precision to secure some measure of these more complex faculties. He also increased the number of different functions measured, hoping thus to secure a measure of general mental ability. The Binet scales involve the fundamental ideas underlying all tests of mental ability and some aspects of personality widely used today.

Many revisions of the Binet scale have been made. Of these, the most widely used have been the Stanford Revisions by L. M. Terman in 1916, and in 1937. A number of modifications and improvements were included in the Stanford-Binet Scales. The number of tests was increased to cover a wider range of abilities, and there was improved standardization of the methods for giving and scoring the tests. Terman also divided the mental age by the chronological age to express the relationship between the two ages. The resulting value was called the intelligence quotient, or I.Q. This quotient has been found to remain fairly constant within certain limits.

With the Binet technique only one subject could be tested at a time. This led to a further modification in the development of group intelligence scales. The First World War, with its pressing need for securing a rough classification of thousands of men in a brief period, stimulated the preparation of a test for measuring the general mental level of large groups of men at the same time. This task was entrusted to a committee of five psychologists who were trained in the field of mental testing. The committee was under the direction of Robert M. Yerkes. The nature and range of the items included in the test, the relative objectivity in administering and scoring it, together with certain other definite requirements which were met as far as possible by the committee resulted in a fairly reliable and valid instrument which has served as a model for later tests. Since 1920 group tests have been devised for age levels ranging from the kindergarten to the university, and to meet the needs of a wide variety of special groups. Many of these tests have been

carefully standardized and pronounced improvement in reliability and validity has been made.

Classified according to their uses, four main kinds of mental tests have been developed: Achievement Tests, Aptitude Tests, Intelligence Tests, and Personality Tests. Some of these tests have been devised as individual scales, others as group scales. Achievement Tests are designed to measure skills and information which have been learned. They measure present ability. Tests designed to predict later success in some given field, such as artistic, clerical, language, mechanical, and musical aptitudes are termed Aptitude Tests. Intelligence Tests are tests of psychological processes. They diagnose behavior. They are used primarily to determine the strength, precision, or effectiveness of the operation of any mental activity. Some intelligence tests are designed to give a measure of general mental ability, while others are limited to some particular ability, such as verbal, performance, mechanical and motor tests. Personality Tests are tests designed to measure the more general traits of personality. They include rating scales, questionnaires, and projective techniques, as well as certain tests for determining differences in social and emotional traits, and other aspects of personality. Most of the findings in the field of human variation are based on results obtained by means of such measuring devices.

Significance of Individual Differences. In a society founded on principles of equality and in which, in theory at least, institutions have been established to foster equal opportunities for all individuals regardless of age, sex, race, religion, economic or social status people have been loath to recognize and accept the fact that marked differences exist among their fellow beings. Yet these differences present problems which have baffled our keenest thinkers since ancient times and are of greatest significance in modern society. Human variation has made laws and government necessary and has been responsible for the development of educational, religious, and political institutions. Failure to recognize individual differences has resulted in religious, economic and social turmoil and has precipitated countless wars throughout the history of the world.

People are not born equal nor can any amount of training or any kind of environment be provided which will make them so. Both

training and environment tend to accentuate differences quite as much as they foster similarities. Biological factors, too, are responsible for variation between different species and within any given species. Social life is much more interesting and has far more spice because individuals vary widely. While scientists are unable to give a completely satisfactory explanation of individual differences, the facts that have been established are instructive. They indicate that variations have a certain regularity and tend to follow certain laws.

Present-day studies of intelligence and learning have demonstrated marked diversity in capacity for education among different individuals. No educational system can be successful unless adequate provision for these differences is made in both subject matter and methods. An educational system organized and administered on the assumption that all individuals are equal cannot be efficient. However, pupils do not fall into easily distinguished and fixed categories to aid the schools in differentiating instruction. In most all traits, they vary by insensible degrees and within widely separated extremes. These facts present countless administrative and instructional difficulties to educators. Nevertheless, differentiated educational procedures are imperative if due recognition is given to the unique potentialities of each child.

In business, also, careful study must be made to adjust men and jobs if waste of human energy and materials are to be avoided. For most satisfactory results, men should be placed in jobs for which they are suited by intelligence, interest and aptitude. Business men have invested enormous sums in perfecting machinery and methods of accounting and salesmanship only to lose larger amounts by their unwise selection of men to operate the machines effectively. Employment psychology is based on the assumption that men show wide variation in specific capacities and skills due to environmental influences, including training, and hereditary constitution. Employing men of superior intelligence in unskilled labor results in industrial unrest. Interest is a major factor accounting for the notable difference in level of attainment between men and women in business and industry. Many women expect their employment to be temporary, and as a result, are uninterested workers, while most men plan to remain in their chosen vocations. They take their work

more seriously and usually become interested in it.

Government and military leadership, too, usually has been in the hands of a limited class of men. Among primitive peoples, physical strength and prowess are the chief basis of civil and military leadership, while among more highly civilized peoples mental and moral qualities receive greater emphasis. In all cases, however, leadership has been in the hands of individuals who are superior to the masses in some respects.

Individual differences are a potent factor resulting in widely divergent views characteristic of political parties and countless political and governmental policies. In consequence some individuals or groups are violently for and others no less violently against particular issues. Laws are passed to please noisy minorities while the silent majority is opposed to the law with resulting conflict between law and social reality.

Human beings differ greatly in the fundamental, biological requirements of food, exercise and sleep. What is suited to one person may be detrimental to another. Drugs do not affect all alike, and susceptibility to fatigue varies widely.

Wars disclose marked variations in the ability of men to withstand frustration and privation. The resiliency of the human organism is noteworthy. Human beings can tolerate an enormous amount of strain without loss of sanity, but here also great diversity has been noted. Some people have been known to withstand very critical and trying crises only to develop greater poise, while others show marked mental disturbance in far less difficult situations. There is little in the life of human beings that is not influenced directly or indirectly by individual variations.

Nature and Extent of Differences. Most human variations are a matter of degree not of kind. They are quantitative rather than qualitative, although qualitative distinctions based on socially-determined criteria are frequently made, as when we speak of a pleasing voice, a wholesome personality, or good moral standards.

Scientific findings with regard to individual differences are often at variance with popular conceptions of the nature and extent of them. The "type" theory has been commonly accepted as descriptive of differences in physique, mentality, and other aspects of personality, since it simplifies the problem and serves as a short-cut

in understanding human nature. People are classified as tall or short, bright or dull, good or bad. Each classification involves sharply contrasted opposites, easily construed as antithetical, dichotomous categories. The typologists assume the facts of human nature to be discontinuous in distribution; each separate case is pigeon-holed as of a given type. A compartment scheme of two, seldom more or less, distinct types would suffice for most human characteristics that are discontinuous, as, e.g., the number of hands or ears. Most aspects of human nature cannot be described as all or none, this or that.

The dichotomous division of continuous traits doubtlessly resulted from the ease in differentiating the extremes in many traits. While it is easy to differentiate giants from dwarfs, or geniuses from idiots, it is often extremely difficult to discriminate slight degrees of variation in both height and intelligence. Some psychologists have contributed to the fallacious dichotomous grouping by placing undue emphasis on extremes of personality, e.g., as when they divide persons into introverts and extroverts, ascendants and submissives, or into verbal and mechanical types. A recent attempt to divide personalities into definite dichotomies is Kretschmer's physical types, the pyknic and the asthenic, each physical group with its own exclusive psychological characteristics. Spranger attempted to classify people into six types which were said to be fundamental and largely predetermined in human nature. These six so-called natural and pure types are the economic, the esthetic, the political, the religious, the social, and the theoretic. However, perhaps no one ever represents a strictly pure type. Spranger's type classification does not have a physical basis, and it was not founded on clinical or experimental study. It was abstracted from the study of history and literature. While interesting, there is little of value in such attempts since they do not conform to experimental findings.

Most human variations are not discontinuous and qualitative, but continuous and quantitative. If grouped in class intervals, they follow a normal bell-shaped curve of distribution known as a frequency polygon or curve. The majority of cases cluster about the midpoint of the curve with a continuous gradation from one extreme to the other with no gaps or breaks in the curve. It is uni-modal rather than bi-modal, tri-modal, or multi-modal, as affirmed by vari-

ous type theories. The curve also is bilaterally symmetrical, with approximately equal numbers falling on either side of the perpendicular erected at the center of the horizontal base line.

Under special environmental conditions, it is conceivable that two groups with little overlapping of certain traits might result. This might be the case in cultures fostering two extremes of social attitudes, linguistic abilities, dietary habits, or educational environments of widely varying degrees of richness. Such conditions and comparisons, however, are the exception rather than the rule. They tend to bring the abnormal into sharp relief by contrasting the two extremes rather than delineating the range of human diversity.

The extent to which intelligence varies is now measurable by statistical methods. Not only has proof been given of variability, but also approximate numerical equivalents of various degrees of normal and abnormal capacities now are available. If measurements are made of the ability of a large random sampling of the population to achieve on any given task or tasks and the results properly tabulated, the scores will be distributed along a normal frequency curve. A few persons will show low achievement, with the number increasing gradually until the midpoint of the curve is reached. Thence, the number will steadily decrease until the opposite extreme is reached, at which point a few persons will exhibit exceptional accomplishment.

If the data compiled are derived from the measures of a single task, the resulting curve illustrates the distribution of a special ability. In forming our present concept of general intelligence, samples of various kinds of ability are taken. If all scores for any given individual fall near the norm or midpoint of a large random sampling of persons of like age and sex, we may conclude the individual measured is an average or typical person. If he should fall decidedly above or below the norm for his group, he is considered superior or inferior, respectively, in the abilities measured. A third individual may show a wide diversity of scores in the various abilities measured. Such a person is said to be uneven, and is often unpredictable, in his capacities.

The principle of deviation is clear, though just how far one may deviate above or below the norm before he is designated abnormal is largely a matter of arbitrary definition. Data for

intelligence ratings, metabolic rate and glandular function of a large unselected sampling tend to follow the normal curve, with the majority of persons rating average. The points above and below which individuals are considered abnormal are fairly well defined for these traits or conditions. Normal intelligence is commonly designated in terms of the intelligence quotient. A person whose intelligence quotient falls below 70 is considered mentally deficient, while one with an I.Q. above 130 is designated very superior. Likewise, most people have metabolic rates near the basic or average point of zero. A deviation above plus ten or below minus ten is considered abnormal. However, there is no general agreement how far one may deviate from the normal on such traits as aggression or submission, introversion or extroversion, or nervous stability and instability, before he is designated abnormal.

In some traits the degree of variability is relative to a given culture or norm. The statistical norm is not relevant to all types of data nor from all points of view. People with some degree of drug addiction, syphilis, brain tumor or cancer, are deemed abnormal by most Occidental social groups. The presence of a causal agent producing mental disturbance in any degree is considered abnormal in many cultures. Moral and ethical standards, likewise differ for different cultural and religious groups, especially the latter.

Factors Influencing Variation. Understanding and control of human behavior must be based on knowledge of the factors which determine variation. Why individuals differ from one another has been a moot question down through the centuries and has led to lively controversy.

The two main sources of individual differences are hereditary background and environmental influences affecting development. Nature-nurture discussions have attracted wide interest and stimulated a broad range of studies. Galton's research which stressed the importance of inheritance in accounting for differences in natural abilities served as an impetus to other workers. Experimental materials and data compiled by biologists and psychologists have contributed to an understanding of the two sources of human diversities, and have afforded a basis for educational philosophy and method.

Not only do both heredity and environment influence human traits, they also mutually affect

one another. It is impossible to differentiate human attributes as those resulting solely from heredity and those attributed entirely to environmental influences. The problem thus is one of determining the relative contribution of each. To what extent are traits and activities determined by hereditary conditions, and to what degree are they conditioned by environmental factors? While these two influences never operate independently in determining human development, it will simplify the discussion to indicate the manner in which each affects organic structures and their functions.

Heredity. The sciences of genetics, especially the gene theory of inheritance, has contributed greatly to an understanding of heredity. A human organism originates in the union of two germ cells, one from each parent. These two parent cells contain many distinct and diverse substances, called genes, which are now believed to be the biological determiners of human variations. There are hundreds of thousands of genes in each germ or parent cell and, with the exception of identical twins, no two individuals have identical sets of genes. Individual parents do not produce germplasm. It is continuous from generation to generation, and is transmitted through parents to their offspring. The child inherits genes not only from his parents but from all of his direct ancestors. This continuity of genes through many generations, the very large number of genes in each germ cell, and the enormous variety of possible gene combinations in the complex human organism, explain the great diversity in individual offspring and also why no child ever is exactly like either parent.

Yet only the structure of the organism is determined by hereditary factors. Apart from their dependence upon certain inherited structures, activities and functions are not innately determined. These facts discredit the theory of the inheritance of acquired characteristics. No plausible explanation has been made which would indicate how the abilities or the knowledge acquired by either parent could bring about a change in his germplasm and thus be transmitted to his offspring. The presence of any given structure does not of itself insure the development of any particular kind of behavior, although the absence of the necessary structure will prevent its appearance. The nature and degree of development of various structures and

of the total organism will affect their functioning.

The earliest systematic investigations of the influence of heredity were made by Francis Galton and reported in his *Hereditary Genius* in 1869. He used the family history method and the correlational method, two methods widely used today, in studying the careers of the relatives of almost a thousand eminent men. He found these men to have relatives of a similar degree of eminence in numbers far greater than chance would allow for average men. In fact, he found the probability of an eminent man having an eminent male relative to be more than one hundred and thirty times greater than for ordinary men. In light of this finding Galton concluded that human abilities are inherited. However, he did not deny the influence of environment and training, and he admitted that nature and nurture cannot be isolated from one another and assigned definite values.

Later studies have shown higher correlation between physical and mental traits of identical twins than for fraternal (non-identical) twins. These data substantiate further the belief in the potency of inheritance in determining the characteristics of an individual, since identical twins develop from a single fertilized ovum whereas fraternal twins result from the simultaneous development of two different cells.

From the standpoint of heredity, the similarity between non-identical twins is no greater than for ordinary siblings, and yet the average coefficient of correlation between the measures of most traits is considerably higher for non-identical twins ($+.70$) than for ordinary siblings ($+.50$). If the traits correlated were wholly a matter of genetic determination, the correlations between non-identical twins should be no higher than between siblings. Hence differences between these two groups, would seem to be the result of greater similarity in environmental influences, the prenatal fully as much or more than the postnatal influences. This fact also corroborates the belief in the complexity of the nature-nurture controversy and the futility of attempting to disentangle the specific contributions of heredity and of environment to achievement.

Environment. The effect of environmental conditions in accounting for individual differences may be considered from two points of view: first, the period of development, whether

well as the level of mentality of parents and their offspring.

Differential Factors. The various factors that influence human variation may be conceived as the joint product of heredity and environment, or nature and nurture. Such biological factors as age, sex, and race as well as family background may be attributed to heredity, while the cultural, educational and social agencies which mold the individual's development from birth to death are environmental influences. These factors will be considered in turn, and the differential aspects of each briefly analyzed.

Age. Not only are individual differences found in human infants at birth, but these differences become more pronounced as the child matures. Marked variations in size and weight, as well as in contour and proportion of body structures may be noted. Growth is very rapid during the first few years, even though not all aspects of growth occur at the same rate. Growth in height is more rapid than growth in weight and breadth. The weight at birth is doubled during the first six months and trebled during the first year after which the curve of weight continues to show definite negative acceleration.

Vital organs such as the liver, lungs, kidneys, heart, and brain grow at different rates—most of them showing a period of acceleration followed by periods of retardation. The nervous system, especially the brain, develops most rapidly during the prenatal period. At birth the head is relatively the largest part of the body and is the first bodily structure to attain mature size. Such changes are due primarily to maturation—the growth and development of innate characteristics.

Numerous studies have shown a striking regularity and orderliness in the development of behavior patterns during the early weeks of life. While specific behavior patterns develop uniformly during this period, pronounced individual variation in the time of their appearance has been noted in different children. Certain basic uniformities in development occur in all infants, whether normal or abnormal, superior or inferior, even though the growth curves disclose individual variations to be relative from the early months of life throughout the early years of childhood.

Variation in the mentality of children has long been recognized, but only in recent years

have standardized scales been devised to measure mental growth changes. The scales are designed to give a quantitative statement of increased mental ability, and the results are used as a basis for predicting the future development of the subjects tested. The intelligence quotients of most children tend to be relatively constant, but the maintenance of relative rank among children, while marked, is not universal. Nevertheless, it is significant from the standpoint of education that each child tends to maintain his relative position of inferiority, mediocrity or superiority in general mental ability.

Most traits of a given individual show positive correlation, even though sometimes the correlations are low. Linguistic and mathematical abilities usually correlate most highly with general intellectual level, while art and musical aptitudes exhibit the lowest correlation.

Mental growth, like physical growth, is not symmetrical; it varies in rate at different ages. Most studies show a continuous increase in mental capacity through adolescence, at least to the age of twenty or beyond. There is considerable evidence to indicate that inferior individuals for the most part tend to mature earlier than normal ones, while superior persons probably mature later, though exceptions have been found. Some time after the age of twenty a slow decline in intellectual capacity usually sets in, becoming marked after fifty. Here again individual variations are pronounced.

Emotional growth and the development of character traits are other aspects of personality which manifest marked diversity. Their rate of growth and level at maturity will often exhibit little or no correlation with maturation in general intellectual capacity or with educational achievement. Character development is a slow process and continues well into adulthood. It tends to be more modifiable than physical maturation and level of mental capacity, and individual variations are very great at all ages.

Sex. The problem of sex differences has attracted perennial and widespread interest. A vast amount of literature on the subject has been published. The inferiority of the female is a popular belief universally accepted since ancient times. Discriminations on the basis of sex have been prevalent in all races in educational and vocational opportunities and are not uncommon even at the present time. Specialization and division of labor are characteristic of

all cultural groups. The particular duties assigned to each sex differ widely in various groups and not infrequently are reversed in varying cultures. The common belief in hereditary sex differences, particularly in mental and emotional traits, and the necessity for assigning special roles and tasks to each sex, is centuries old. To attempt to train women to the level of achievement attained by men has been considered futile. That existing sex differences may result from restrictions imposed upon women from infancy, especially in the educational and vocational opportunities open to them, has been overlooked.

Most scientific studies relating to sex differences agree on certain important findings. Although boys are taller and heavier at birth and at adulthood than girls, girls mature earlier than boys, anatomically, physiologically and mentally. In the early years of adolescence, girls are taller and heavier than boys. In girls the trunk is relatively longer and the limbs relatively shorter than in boys. Girls tend to have a greater amount of fat while boys have more muscle. They reach puberty at least a year or two earlier than boys. Girls' bones ossify earlier, and they cut their permanent teeth earlier than do boys. The thyroid gland appears to play a more important role in girls, and thyroid disease is more common in women. The removal of the thyroid gland in lower animals has shown more pronounced effects on the development of females than on males.

The results of mental and scholastic tests indicate that mental development at least from early childhood to adolescence, also proceeds more rapidly in girls than in boys. As they approach adulthood however, the average scores on general intelligence are strikingly similar, although many studies have shown greater variability in males. A greater number of very low scores as well as a greater number of very high scores seem to be made by men than by women.

History has recorded many more outstanding men than women in practically all lines of endeavor. Men have been the leaders not only in military and political life, in business and industry, but also in science, literature, music, and art as well. In light of the social status of women in the past, it is not surprising, indeed, it is to be expected, that such should be the case. Biological differences and cultural taboos

have forced women to devote an undue amount of time to home-making and child-bearing. Men, on the other hand, were drawn into a richer and more stimulating environment, contacts which necessitated training, while women were forced to subordinate their interests and ambitions to the careers and aspirations of their husbands. Custom has barred them from competing with men. Even today women in some primitive societies live in a cultural vacuum.

Any interpretation of sex differences on the basis of test results must take into account cultural differences between the sexes and the limitations in training and opportunities for women. Many differences now found might disappear were it possible to equalize all conditions for both sexes from birth through maturity. Not all differences between the sexes listed below should be considered as innate in origin.

The distribution curves of test results for the two sexes usually are decidedly overlapping, but for some aspects of behavior consistent and reliable differences in averages have been found. Men are usually superior on tests of reaction time, speed of tapping, muscular strength, and coordination and dexterity with tools, while women excel in speed of word association, quick adaptation and shift of attention and on tests involving finger dexterity. Women appear to be somewhat superior in tests of color discrimination, and color blindness is more commonly found in men. In most other sensory capacities, sex differences are either very slight or wholly absent.

In tests on school subjects, men show consistent superiority in mathematics, science, and history, while women excel in English and reading. Men also tend to be superior in sustained logical work and spatial thinking but are definitely inferior to women in most memory and verbal tests and on tests of number-checking and pattern-recognition. Differences in memory and verbal ability favoring girls are evident in the preschool period and persist throughout life.

Race and Nationality. The measurement of group traits especially racial and nationality characteristics, presents a host of difficulties, many of which appear to be insurmountable. On superficial thought, it would seem to be a relatively simple matter to obtain a representative sampling of any given race or nationality,

for the superficial thinker accepts the popular classification of races based on skin color. Thus we have five main groups: white, yellow, red, brown, and black. From an equally superficial viewpoint one's nationality is determined by the country (geographical area or cultural or political unit rather than biological grouping) of one's birth, or at most by the birthplace or places of one or both parents or grandparents. In truth, however, the problem of defining either race or nationality becomes extremely complex and baffling. They are problems fraught with countless pitfalls. Inter-marriage between individuals of different races and nationalities and all manners of cultural intermingling which have gone on all over the world for centuries have resulted in the disappearance of most if not all pure racial and nationality groups.

To complicate further the problem of securing reliable data, race and nationality prejudices, even to point of extreme hatred, are encountered on every hand. Membership in a group confers superiority on that group. Its members are the chosen people, excelling all other groups in the many aspects of its culture. Other groups are inferior in so far as they differ—the more marked the differences, the greater the inferiority. Race prejudices have existed through the ages, especially where unlike peoples have been forced to live in close proximity to one another. Worse still, these prejudices all too often lead to violent conflicts between races and nations. The disturbed world conditions of the twentieth century, with their marked social unrest and bitter political controversies, have accentuated emotional behavior. This prejudice and the heightened emotional tension has made it extremely difficult for even the scientifically trained student to maintain a disinterested and impartial attitude and arrive at unbiased conclusions.

More difficult still is the attainment of a truly random sampling of any one race or nationality even when they are defined. To secure comparable samples of two or more such groups is even more difficult, if not indeed impossible. Many races have been studied in which the word "race" was not used in any scientific and ethnic sense. More serious, for many of the groups, the samplings have been too small to possess statistical reliability.

The selection and standardization of test

materials, the techniques for administering and scoring the tests, and the norms for interpreting the results obtained from the measurement of groups varying widely in cultural background and in opportunities and standards of training and experience, present difficulties which baffle the keenest minds.

To secure even a measure of reliability, all data on racial and national comparisons should be evaluated in the light of at least three criteria: (a) the sampling of the given population considered, (b) the conditions under which the data were collected, and, (c) analysis of the statistical methods employed in interpreting the data. In the brief summary of findings on race and nationality differences that follows results will be cited only when there is evidence that the above criteria have been conformed to as closely as possible. Since any criteria that may be used for either are at best approximate, no attempt will here be made to define either race or nationality, much less to classify them into a limited number of groups.

In analyzing the more reliable findings resulting from these studies one is impressed with (a) the wide variation within any so-called race or nationality for any trait studied, (b) the marked overlapping of any two groups on any given trait, and (c) the lack of any consistent cluster of traits which characterize any group.

A number of other fairly reliable differences disclosed by various studies merit consideration. As regards physical differences, variations in skin color are the most obvious. On the other hand, differences in facial and cranial measurements and in stature are surprisingly small for different groups. Such characteristics as shape of the skull, facial features, and stature have been found to depend to some extent on influences in early infancy, and on various later environmental conditions. Hair and eye color are also variable, but even these as well as stature may be affected by climate, disease and diet. Available evidence indicates that the average weight of the cerebrum in Whites is approximately 10 per cent heavier than in Negroes.

As regards differences in sensory as well as in the more elementary motor processes such as rate of tapping and handedness, for example, no significant differences between different nationalities have been found.

Many attempts have been made to study differences between racial and nationality groups

in the higher mental processes, in light of the results obtained by intelligence tests, especially group tests of intelligence. Group tests require a high degree of cooperation and adjustment of the subjects to the examiner. Since directions must often be given to the testee through the medium of language, and sometimes even by gestures, the results obtained may be a measure of the examiner's ability to make his instructions clear quite as much as of the subject's ability to comprehend and carry out the instructions. An individual test is more satisfactory than a group test in cases where language handicaps are encountered.

Even when very carefully constructed, most tests are influenced by cultural and educational factors. Consequently, at least some of the differences found between groups may be attributed to variations in cultural level and social heritage rather than to a native inferiority. This fact has been demonstrated in studies in which comparisons were made between the intelligence of groups of American Indians and white children on the basis of tests devised by Whites and standardized on a sampling of the white population. The Indian groups, although varying from tribe to tribe, rate consistently lower than Whites on verbal tests, whereas they are but little, if at all, inferior to Whites on most performance tests when scored for errors and not for speed. The emphasis placed upon speed varies greatly in the two cultures. The Indian is handicapped when speed becomes a factor in determining the results of test scores. The inferiority of Indians on verbal tests likewise may be attributed to social heritage, since the test scores tend to increase as the cultural level and educational opportunities approximate that of the white population. An increase in intelligence test rating also has been found for mixed bloods, with a steady rise from three-quarter-bloods through half-bloods to quarter-blood Indians.

Negroes in America invariably rate lower than Whites, and Southern Negroes lower than Northern Negroes. Authorities in the field now attribute the former to superior educational and social advantages rather than to innate superiority on the part of the Whites, and the latter to the tendency for the inferior Negro to remain in the South. As in the case of the American Indian, the inferiority of the Negro is most marked on verbal tests. On some performance

tests, however, his scores approximate those of the Whites.

For the European immigrant groups a reliable difference has been found between the mean scores for the descendants from northern and southern countries, though here again there is a marked overlapping of scores. This difference, while small, favors the offspring of northern Europeans. None of these immigrant groups are comparable, nor are they a fair sampling of their native countries. Many selective factors operated to bring their ancestors to America.

Children of immigrants from China and Japan test on a par with native-born white children in the United States. Some minor differences have been noted for certain abilities, but these differences tend to disappear in the second generation of immigrants.

A careful survey of the major studies in the field seem to indicate that racial and nationality differences have been greatly overestimated. There is a wide range of ability within each group. Many Negroes and Indians surpass the average of the Whites. On the whole, it would seem that most racial and nationality differences in mental ability would be negligible or would wholly disappear were it possible to equalize educational, social and all other advantages from earliest infancy onward. A problem worthy of the most serious consideration for educators, social workers, and others concerned to promote international amity and understanding is the improvement of means for developing and utilizing the abilities latent in the underprivileged groups in our midst.

Family Background. As noted earlier, Francis Galton employed the family history method to investigate the role of heredity in determining natural abilities. He compiled data on physical measurements of parents and their children. He found an average correlation of $+0.52$ between parents and their offspring for such bodily characteristics as length of forearm and height. A similar average correlation has been found for siblings on physical traits. The correlations on these traits decrease for grandparent-grandchild and cousin relationships and increase for fraternal and identical twins. The similarity in physical traits in members of the same family results, for the most part, from their common heredity. When children selected at random are paired as siblings the average correlation for the above traits is about zero. However,

when unrelated children are paired in terms of similarity in background the average correlation is about $+0.35$. The average correlation in I.Q.'s between foster children reared in the same home, and between the foster children and the cultural status of their foster homes, are positive but low. These facts suggest that environment affects mental traits in some degree.

Thorndike has reported a correlation of $+0.60$ for siblings for scores on a battery of tests designed to measure general ability. Similar correlations have been found in other investigations. The average correlations between parents and children on most mental tests tend to be somewhat lower than for siblings. This fact would again suggest the influence of environment which is more constant as a rule for siblings than for parent and child. Correlations between siblings and even for identical twins vary widely on tests of special abilities when the ability measured depend upon environment and training. Some studies also have shown a tendency for the scores of children (both boys and girls) to correlate more highly with the score of the mother than with that of the father. Contrary to common opinion, no consistent differences have been found between the scores for parents and either like-sex or unlike-sex children. Neither daughters nor sons tend to resemble one parent more than the other.

Another physical factor that is sometimes claimed to affect the ability of the child is the age of the parents at the time when the child is born. It is commonly believed that children of young parents suffer both a physical and a mental handicap. An increase in mental rating has been found for children with increase in age of parents through the late twenties, but this increase in score tends to disappear when differences in social background are eliminated. It is evident that, in addition to inferior heredity, inferior living conditions such as inadequate nutrition, poor sanitation, fatigue, and worry during the fetal stage of development may handicap a child. Children of young parents of superior social status usually are more intelligent than are children of older parents in underprivileged groups.

The differential birth rate in families of different social status presents a serious problem for social workers. The average mental rating for children of large families has been

found to be consistently lower than for the children of small families, but, unhappily, the average mental level of the parents of large families is also lower than that of parents of small families. No reliable differences in intelligence have been found between first-born, middle and youngest children.

Ancient lore is replete with beliefs concerning astrological influences associated with the month or season of birth. Popular interest in this subject has persisted down to the present day. Perhaps for no factor in the family background here considered has more pseudo-scientific information been published. Carefully controlled studies have been made in which data on the season of birth were compiled for samplings of different racial groups and the results are consistent. The findings indicate that not only are more children born during the first three months of the year due to a seasonal sex rhythm, but also that the variability in intelligence is greater during these months than for other seasons of the year. The average I.Q. for children born in January, February, and March is slightly but significantly lower than during other months. There are also more children of very superior and of very inferior mental ratings born during this three-month period. No satisfactory explanation of these facts is as yet forthcoming.

Consistently reliable differences have been found for the mental scores of children of parents at various occupational levels. The average intelligence rating of children whose parents are engaged in the professions is significantly higher than the average score for children of skilled workmen, and these in turn rate consistently higher in mentality than children of unskilled laborers. Both heredity and environmental factors enter into the determination of the mental ability of any individual. Data compiled during the first World War indicate that there is marked overlapping of intelligence scores in most vocations. Some unskilled laborers have higher mental ratings than some professional workers. Nevertheless the higher the fathers' occupational status, the higher is the average intelligence level of the children. There is a significant positive correlation between the intelligence rating of children and their fathers' vocations. The correlation, however, $+0.30$ is low. Since test results show a wide range of scores it is clear that there are pronounced

ences which surround and mold the individual from earliest infancy through adolescence and beyond are also major determinants of personality.

No single aspect of one's environment can be distinguished as the determining factor of any definable aspect of personality. Rather, it is the totality of the culture pattern or complex areas within those patterns, which mold the personality of the individual. Character, for example, cannot be attributed wholly to religion, training, social or economic status or any other apparent factor in the cultural or environmental background. All traits of personality and integrated patterns of traits are a product of the totality of environmental influences, customs, culture products, attitudes, and other social forces to which the hereditarily unique organism reacted, and the way in which it reacted in the process of development.

Human variations are extremely complex. They have their roots in psychophysical dispositions and conditions which are the result of both heredity and environment and which impinge upon the individual in countless ways. There are many and very vital relationships in any person's background which should be evaluated in analyzing the determining factors of his variations. The essential factor or factors in determining human variations does not seem to be closely related to any particular aspect of heredity or environment, but rather to the total nature of the individual and his relation to the total character of the environment, psychological and material, in which he has functioned. Thus, it is apparent that individual differences are limited only by the number of different individuals and groups and the nature and extent of the variations in traits and combination of traits which characterize them.

INDIVIDUAL PSYCHOLOGY: ADLERIAN SCHOOL.—*History and Relation to Different Branches of Psychology and Psychopathology.* Alfred Adler was born in Vienna, Austria, in 1870. He went to medical school at the University of Vienna where he received his M.D. degree in 1895. Thereafter, he devoted himself to general practice. His first major publication dealt with working conditions of the tailor trade, pointing out some of the professional dangers to the health of those engaged in this profession. Soon after this, he became interested in psychiatry and began to devote his entire work to psychiatric problems. In 1902, upon the invitation of Freud, he joined the latter's circle. From the very beginning Adler hesitated to join, since he never agreed with the Freudian interpretation of symptom formation of the neuroses. At that time Freud insisted upon the all-importance of sexual traumata for the causation of neuroses, where-

as, Adler had already started elaborating upon the problem of the influence of physical disability upon mental development. In the beginning however Freud encouraged collaboration in spite of the fundamental difference in views and interests. In the following years, this pre-existing difference became more acute during the discussions of the group, and in 1911 Adler left the circle with seven of his followers. The breach was precipitated by Freud's demand to have publication of articles in the journal of the group, whose editor Adler was, dependent on Freud's approval. During the first year after the secession, Adler's group was called the "free psychoanalytic" movement. In 1912 he coined the name "Individual Psychology" for his new psychology. With this name he meant to imply that in order to understand the structure of the personality, in each individual case it was necessary to explore what special meaning interpersonal relations had for that particular case. This tendency was especially exemplified by the Individual Psychologist's effort to explore the personality as a whole which, thus, was opposed to tendencies of psychoanalysis and other trends of psychology to evaluate performance and symptoms as individual entities in themselves. This attitude has elements similar to those of the Gestalt theory and many consider Individual Psychology a practical application and elaboration of the Gestalt theory. Since Individual Psychology (henceforth to be referred to as I.P.) stresses the necessity of taking into consideration the relations of the individual to all the environmental problems as well as intrinsic factors related to physical stimulations or handicaps, it is closely related to Adolf Meyer's psychobiology. The most important link between I.P. and Freudian Psychoanalysis is the stress on the importance of unconscious motivation upon performance and symptomatology. I.P. implies depth psychology, since it is not based on mere description or summary interpretation of personality and personality difficulties, but in each instance explores the deeper roots which are then probed as to their validity to explain the structure of the whole personality.

SUBJECT MATTER OF INDIVIDUAL PSYCHOLOGY

I.P. has been used in various branches of medicine, psychology, history, and literature. In the field of psychiatry and psychology, espe-

cially, it has contributed to the understanding of the normal and abnormal personality development. It finds its practical application in the psychotherapy of the neuroses and, in particular, in child guidance.

THEORY OF THE NEUROSES

1. *The Theory of Organ Inferiority and Its Psychic Compensation.*

The theory of organ inferiority formed the starting points of the individual psychological interpretation of the neuroses. Here Alfred Adler explored the influence that an organ, which is handicapped either through organic defect or through deviation of function, may exert upon the mind. In his writings he pointed out that the mere idea of being subject to a physical or to a mental inferiority was likely to exert the same influence upon the mind as if such an inferiority really existed. Such handicaps may result in either of two diametrically opposed reactions: A person may, on the one hand, react with a defeatist attitude to a handicap and succumb to it. This, for instance, may happen in left-handed children who live under the impression that they are awkward and, consequently, give up trying to use their hands skillfully. In later life they may shift all the responsibility for manual activity to others and may use their congenital defects as an excuse for such reaction. People who act in this way are suffering from an "inferiority complex" which means that they over-react to a handicap. This inferiority complex should not be confused with the "feeling of inferiority" which may act as a normal stimulus, particularly in the growing child, who thus is directed toward emulating to achieve grown-up performance. On the other hand, a handicap may result in greater efforts and interests to overcome such a difficulty. Consequently, such persons may compensate and even over-compensate a given inferiority. On the physical side such development is exemplified, for instance, through the finding of a hypertrophic heart and skeletal muscles which develop under the necessity to overcome obstruction or weakness in other parts of the system. Alfred Adler and his pupils have quoted numerous instances of compensatory processes through mental and physical effort. They pointed to the, by now, popular examples

of orators like Demosthenes who had been stammerers; musicians like Beethoven, who suffered from congenital ear disease; and sculptors and painters, like Michelangelo, who were left-handed. Analogously, they showed that an individual may feel stimulated to overcome a psychologic situation where he feels held back and slighted and may achieve superior results. Thus, Alfred Adler was one of the forerunners of that branch of modern so-called "psychosomatic medicine," which studies the influence of the body on the mind.

2. *The Fictitious Goal of the Neurotic*

In interpreting the symptom formation in neuroses I.P. bases upon the doctrine of the finality of human performance, be it on the conscious or unconscious level. I.P. differs from other trends of psychopathology which look for traumatizing events in the past—which more or less fatalistically are supposed to lead into neurosis—in that it points to numerous observations which imply that the actual events are of no definite importance for later development. It is the use or misuse a particular individual makes of these events that is stressed! To understand the reaction to the events, the individual goal has to be investigated. The sum of the various responses which lead towards this fictitious goal was called the "style of life." Consequently, it may be said that in one case the style of life corresponds to that of an individual whose goal is directed toward useful accomplishments, whereas in another it may be directed toward activities on the useless or anti-social side. For instance, in many neuroses the goal may be to achieve protection from the challenges of life in order to be excused from social, professional, or marital obligations. The basis of such formation was found to lie in a discouraged attitude of the individual rooting back into childhood. The formation of the individual style of life and of the goal is the result of procedures arrived at by the trial and error method. The individual finally stresses what to him seems to be the most successful approach to the solution of his problems. Since in the neuroses the way of arriving at such results is different from the normal way of thinking and acting, the neurotic or psychopath is said to base his reactions on his own "private logic."

3. *Symptom Formation in the Neuroses.*

In order to understand the meaning of symptoms in the neuroses, it has to be explored what use the patient is making of symptoms or, in other words, what particular goal the patient achieves with his symptoms. Often insight into this problem can be gained by directly asking the patient what he would do if he were not suffering from the symptoms in question, for instance, if he were not suffering from fears of crossing open places, compulsion to wash his hands, fear of blushing, and the like. The answer of the patient, usually implying that he then would get married, continue in his profession, take up social relations with his friends, or meet any other challenge, explains the meaning of the symptom in that particular individual. Thus, neurotic symptoms serve the patient as a screen behind which he hides so as to be excused from the "firing line of life." The answer of the neurotic is formulated as the "yes—but" approach. In acknowledging the demands of life the patient follows the general logic of mankind. But through his neurotic symptoms he excuses himself for not following suit. So, for instance, a neurotic would say, "yes," he knew that he should seriously consider marriage to his partner "but" his constant fear of blushing prevents him from taking the necessary steps.

As in other branches of depth psychology, considerable attention is paid to tracing the development of the neurosis back to early life. In summarizing these investigations a type was found described as the "potential neurotic child" which was most likely to develop neurotic symptoms later in life. Such children are rather obedient, peaceful, and obliging but have difficulties in their contacts with playmates and in following some other routine procedures. Their early attitude parallels symptoms found later in the neurotic. Thus, such children will try to join their playmates and follow their obligation in school and at home, "but" they will soon bring about reasons why they should be excused from certain activities. Those are the children who complain of their playmates being too rough, that they are too tired to do any work at school or at home, who vomit their breakfast and consequently feel unable to go to school and similar obligations. This is the early training of the potential neurotic which gives him

the experience of how to be excused from the demands of life through certain symptoms. Since the results mean success to the neurotic, according to his style of life, this pattern is gradually adopted as the basis for the neurosis in adult life.

4. *The Neurotic Character.*

I.P. does not consider character as an inherited structure but rather as the sum of the various situational responses, constituting the unified personality. Deep-seated vanity has been established as one of the main characteristics of the neurotic personality. This results in a constant fear of failures. Since life is full of possibilities of failure such patients are in constant fear. This trend was found to be the result of early discouraging experiences which gave the child the impression that he was unable to equal performance of his environment, and thus led to an inferiority complex. This, in turn, may be caused by experiences in any field and usually not only by one experience but by an accumulation of experiences in any field of contact, which may be misinterpreted and so, secondarily, made into causative factors of neurotic development. Around this fundamental vanity other characteristics, such as jealousy, maliciousness, stubbornness, and suspiciousness are grouped, completing the character of the neurotic. These characteristics are the result of the ever-present tendency of the neurotic to depreciate others in order to feel superior by comparison. In addition, such patients are often cowardly, fearful, craving for sympathy, and tyrannical in their demands upon others, since they feel helpless without the sustained protection of their relatives or friends.

5. *Social Interest.*

An additional differentiation between the normal, and the neurotic and psychopath has been elaborated by I.P. Normally, our actions are directed, in the final analysis toward achievements that benefit the welfare of the human family. Thus, our actions are controlled by Kant's moral law which postulated that a human being is to act so that the principles of his activities could be made into the fundamentals of a general code of law. In normal people this kind of activity is, in many instances, almost on an automatic level. In the neurotic

and psychopath those inner laws are transformed and circumvented in accordance with their "private logic."

THEORY OF PSYCHOPATHY

According to general usage the term psychopathy includes criminals, alcoholics and other drug addicts, and a variety of misfits suffering from primary difficulties of adjustment. The pattern of the psychopath is characterized as a "no" answer to the various obligations. Such individuals decline realization of moral laws pertaining to the whole of humanity. Instead, they proclaim their own wish fulfillment as of primary importance regardless of the hardship it may impose upon others. Many examples of this kind can be found in history among "leaders" of nations, and in the life history of other notorious criminals. Whereas a neurotic declares it a failure if through his symptoms he is prevented from achieving worthwhile goals, the only failure the psychopath usually acknowledges is being caught or prevented from achieving all of his adverse plans. As in the neurotic, a type of the "potential criminal" has been elaborated. Such children show early signs of revolt, decline responsibilities and fight for what they want to get. The basis of such a pattern is often found in a child's sense of being neglected and the resulting feeling that, unless he forces his environment, he will perish.

INFLUENCE OF EXOGENOUS FACTORS ON DEVELOPMENT

1. *Type of Basic Difficulty.*

I.P. has elaborated on three types of children who are most likely to develop difficulties in later life: the pampered, the unloved, and the child with a physical handicap. Of these three groups the largest is that of the pampered. Such children grow up with the idea that the whole world revolves around them. No difficulties may be realized during childhood which represents a protected period during which adjustments are made to the child by its environment. Disturbances are, however, likely to develop once the child is thrown upon its own resources as he is after reaching a certain age or, when he is deprived of his favored situation. The latter occurs upon the arrival of a sibling. At that time difficulties of adjustment may develop, thus showing that the child has not been prepared

to share with others. Symptoms like bedwetting, destructiveness, disobedience, eating difficulties, and the like may develop as an indication that the child does not feel able to adjust in the normal way.

Unloved children are found particularly among illegitimate children and in broken marriages. Such children miss the most important experience of early childhood, namely, that of a relation to a thoroughly reliable companion, the mother. They grow up as if in enemy's country where they have to fight in order to survive. This is the pattern of early life in many later criminals.

The difficulties encountered by children with physical handicaps have been dealt with above.

2. Position in the Family.

I.P. has pointed to the fact that children of the same family vary considerably according to whether they are the youngest, second-born, eldest, a boy followed by a girl, twins, an only child, and the like. In the following a characterization of these different types is given. The youngest in a family sees ahead of him his other siblings whom he realizes he never can equal when developing at the same rate of speed. Consequently, he often develops as if cast from a different mold. Examples of this type are accounted for all through the ages and nations. For instance, the hero of the fairy tale, "Little Hop O' My Thumb," the youngest of seven brothers, puts on seven-league boots and runs faster than all of the others, through his cunning kills the giant, and liberates his brothers. In many academic families, the youngest becomes a dancer or actor, thus earning his living and achieving independence earlier than his older siblings. On the other hand, such children may develop the desire to stay always "the baby" of the family, being closely attached to the mother and unable to develop grown-up independence. The second-born often reacts as if under constant pressure, having before him the shadow of the older. He often develops faster than average and overruns the older. Frequently, he fights authority and continues doing so in later life, thus courting difficulties with his environment. If directed toward useful channels, however, his ambitiousness may stand him in good stead. The eldest is often conservative as if he wanted to preserve his

position for later life. Accustomed to being an authority among his siblings, he may miscalculate steps in his later life through incorrectly anticipating agreement from other sides concerning his plans. On the other hand, he may develop a great deal of foresight as a result of early training. A boy who is followed by a girl often develops profound discouragement during early adolescence when he suddenly feels overrun by his younger sister since girls develop at a faster pace during early adolescence than boys do at that period. Often gradual failure in school is noticed under such conditions, as an expression of the deep discouragement of the young boy who compares himself unfavorably with his growing sister. Twins, identical twins in particular, are found to be practically always on the best of terms. This is a result of their being treated as equals with the same rights and restrictions. Thus, they realize the benefit of mutual cooperation for common interests. On the other hand, they are often handicapped by their exaggerated dependence upon each other which makes them feel insecure when thrown upon their own resources. Finally, difficulties of the only child were pointed out and have been dealt with previously under those of the pampered child. In all such instances the individual development cannot be predicted. But there are definite problems connected with the position of the child in the family which have to be answered by the child in one way or another. Realization of the existence of these problems is the prerequisite of correctly dealing with them as an educator or psychotherapist.

INDIVIDUAL PSYCHOLOGIC PSYCHOTHERAPY

Extensive use of psychotherapy has been made by I.P. in the treatment of neuroses in adults and children, in child guidance, and in treating psychopaths. The results of psychotherapeutic treatment of the so-called functional psychoses were considered discouraging in the severe cases and conducive to temporary and partial success only in light (which means easily approachable) cases of manic-depressive insanity and of schizophrenia. No attempt at treatment of the symptoms in the organic psychoses as, for instance, general paresis, was ever encouraged by I.P.

Three steps have to be differentiated in indi-

vidual psychologic psychotherapy. First, the psychotherapist has to gain an understanding of the meaning of the patient's difficulties, of his basic conflicts, and of the goal that is to be achieved with the help of his symptoms. Secondly, the patient is made aware of these mechanisms, and understanding and insight have to be given him. Finally, the patient has to be guided in his new ways of adjustment. For the experienced it usually does not take long to understand the basic difficulties of his patient. Usually the first few sessions suffice for this purpose. But the patient does not profit if such knowledge is put before him bluntly. At that stage his conflicts prevent him from dealing with his problems on a conscious level. Consequently, his understanding has to be increased gradually through interpretation of his various performances, of his dreams, and of his first recollections. During the final period, the patient is encouraged and helped to apply his newly acquired insight in his daily activities. During the whole course of treatment a friendly, encouraging attitude is maintained. No attempt is made to develop any closer tie between psychotherapist and patient. On the contrary, any development of dependency is discouraged. I.P. points out that it would be in keeping with the style of the neurotic, who habitually abuses the services of others for his own sake, to let such a dependency develop. Consequently, this would not present anything but a repetition of previous performance and, therefore, implies a loss of time for the patient. In serious cases the patients are seen three to five times weekly, at least in the beginning. As soon as possible attempts are made to diminish the number of the patient's visits in order to enable him to train himself in the use of his recent knowledge. Lighter cases, which means cases that are able to control their thoughts and emotions to a larger extent, are seen at greater intervals, often only twice weekly even at the beginning of the treatment. The patient is told to discontinue treatment after a few weeks unless he himself notices improvement by that time. The duration of treatment varies in each case. However, treatments are hardly ever prolonged beyond the one year, and average several months.

In children treatment is usually of shorter duration, and children are seen at greater intervals than adults. A question frequently asked

is how much insight should be given to a child. This depends upon a child's intelligence, age, and interest, all of which should be used to the limit, but never beyond it, for the explanation of genesis and meaning of the child's symptoms. Cooperation with the parents is a prerequisite in all cases. The child is more dependent upon his parents' relation to him than upon any other relationship. Therefore, treatment of children may prove to be futile unless cooperation of the parents can be secured.

I.P. figures as a pioneer in the propagation and demonstration of child guidance inasmuch as in Vienna up to thirty child guidance clinics were conducted under the supervision of trained individual psychologists. There the first child guidance clinics were opened in 1920. Most of them consisted of a psychiatrist, a psychologist, and either a teacher or a social worker. Most of these child guidance clinics were conducted in close relationship with the various public schools. About 1934 most of these child guidance clinics had to be closed by order of the totalitarian Austrian government. Individual psychologic clinics for adults and children are operated at present in New York and Chicago.

POINTS OF IDENTITY WITH AND OF DIFFERENCE FROM PSYCHOANALYSIS

The most important link between I.P. and Psychoanalysis is the evaluation of unconscious motivation for the formation of symptoms in the neuroses, a procedure based upon early investigations of Breuer and Freud, and of Janet. Both stress the importance of early formative years upon the later development. During psychotherapy, both schools attempt to bring unconscious conflicts to the surface in order to let the patient deal with them on a conscious level. Both schools use dream interpretation, evaluation of early recollections, and interpretation of errors, like slips of the tongue, during psychotherapy. The principles of both schools are "dynamic" and pertaining to the realm of depth psychology. There are, however, many differences between the two schools as to theory and practical application of material. From the beginning of his acquaintance with the Freudian school, Adler had objected to the sexual interpretation of all neurotic symptoms as it was postulated by the psychoanalytic school. Only

recently such postulates were gradually modified, thus effecting an approach between the two schools of thought. In opposing the Freudian views, Adler had always explained that conflicts related to occupational or social spheres may be as pathogenic as sexual conflicts. Moreover, in many instances, I.P. demonstrated that sexual problems represented secondary development related to a primary disturbance of adjustment, whereas the Freudian school postulated a sexual trauma as the origin of mental disturbance. Similarly, I.P. holds that the now popular "Oedipus Complex" is not the cause of the neurotic manifestations but, if present, is the result of any early maladjustment, typically present in pampered children who are unable to share with others. Consequently, they are unable to share the mother with the father but, just the same, they have conflicts in sharing the father with the mother, their playmates with other children, or even inanimate objects like toys with other children. These observations dispose of the sexual interpretation of the "Oedipus Complex." During psychotherapy the development of close dependency, as postulated by the psychoanalytic school as the prerequisite for successful psychotherapy, is discouraged and considered as an attempt on the side of the neurotic to continue his previous pattern. Consequently, by the elimination of this stage much time is gained, and treatment seldom exceeds one year. Other than in psychoanalysis, early recollections are evaluated regardless of whether they are given spontaneously or produced after exploring the realm of the unconscious mind. Another difference from psychoanalysis is that no attempt is made to give such recollections a sexual interpretation, but I.P. points out that such early recollections are an indication of the predominant line of interest of the individual at this early age. Such early recollections, it is contended, are preserved and remembered because of their particular importance for the individual, but not because they are an expression of sexual conflicts. Similarly, there is considerable difference between the individual psychology approach to dream interpretation and its use in therapy and that of Freudian psychoanalysis. At first, Freud explained the dream mechanism as representing a wish fulfillment of sexual desires. This theory was modified only recently when it was acknowledged that conflicts other than sexual in nature might occa-

sionally be responsible for dreams. I.P. explains dreams as the result of open conflicts of the preceding day, these conflicts being related to any possible sphere of life. Consequently, whereas psychoanalysis interprets the different elements of dreams as representing sexual symbols or related to sexual activity, I.P. interprets the dream content on a wider basis. Generally speaking, whereas psychoanalysis stresses the importance of past conflicts, sexual in nature, as responsible for the causation of mental trouble, I.P. elaborates on the structure of the whole personality and its relations to all the important spheres of life which in turn determines the individual use and misuse of past experiences.

MOVEMENT OF INDIVIDUAL PSYCHOLOGY

After Adler's separation from Freud in 1911, several branches of I.P. were formed in the years following, with quarters in Europe and in the United States. At the time of Adler's death, on May 28, 1937, in Aberdeen, England, while he was lecturing at the University, there were twenty-three groups listed, most of them quite active in research and child guidance. The official organ was the *International Journal of Individual Psychology* which was founded in Vienna in 1922 and continued publication until 1938, under the editorship of Alfred Adler. After his death his daughter, Alexandra Adler, became editor until Austria's annexation by Germany in 1938 stopped further publication. The *American International Journal of Individual Psychology* was founded in 1935 with Alfred Adler as editor. Publication has been continued up to date in various forms. At present the *Individual Psychology Bulletin* is the central organ, published as a quarterly. The editorial office is at 24 Wabash Avenue, Chicago 2, Illinois. Dr. Rudolph Dreikurs serves as editor. The war has, of course, interrupted the activity of the European groups. In the United States there are, at this time, active groups in New York and Chicago.

As it goes with most modern trends in psychology, the attitude of different psychiatric and psychology circles towards I.P. also varies from complete acceptance to partial rejection.

INDUSTRIAL PSYCHOLOGY.—The psychology of individual differences is the underlying principle upon which most of industrial psychology is based. Experiment as well as experience proves that people are not alike in basic ability, education, training or personality makeup. Job analyses similarly show that jobs vary greatly in their requirements. One of the major purposes of industrial psychology is to place men and women on jobs that match their abilities and potentialities. By so doing, a more effective use of personnel is made because men are not discouraged by jobs beyond their ability or capacity nor are they left unchallenged by jobs which demand only a part of their capabilities.

The matching of abilities with job require-

ments is accomplished most effectively by a proper use of personnel tests in conjunction with other employment procedures, such as the interview, work record, and application blank.

Mental Alertness Tests. These tests, sometimes referred to as intelligence tests,¹ go far toward a proper matching of men and jobs. Simple jobs, such as assembly, fixed gauge inspection, packing, etc., are usually done most satisfactorily by persons who score relatively low on mental alertness tests. Such jobs are neither boring nor monotonous to persons whose general alertness and ingenuity are not such as to require greater stimulation for complete activity. On the other hand, jobs calling for layout, design, policy making and other activities of this type are best performed by persons scoring relatively high on mental alertness tests. Studies which show experimentally and statistically the facts upon which the above statements are based have been published by Bills,² Pond and Bills,³ Tiffin and Greenly,⁴ and Tiffin and Lawshe.⁵

Mechanical Aptitude Tests. Another type of test effectively used in industrial personnel deals with mechanical comprehension or mechanical aptitude. Under this category are considered tests covering comprehension or understanding of mechanical principles or retention of experience dealing with mechanical contrivances. Typical of such tests are the Bennett Test of Mechanical Comprehension,⁶ the Purdue Mechanical Adaptability Test,⁷ and the Purdue Industrial Training Classification Test.⁸ Tests of this type have been shown to have satisfactory validity for placing men on such machines as conversion machinery in a paper mill,⁹ and in the selection of apprentices and trade school students.¹⁰

Dexterity and Muscular Coordination Tests. The mechanical aptitude tests discussed in the preceding section deal with the *understanding* aspect of mechanical operations—not with the muscular or motor phases of the job. For the latter, dexterity tests have been found more usable. Typical dexterity tests are the O'Connor Finger Dexterity Test¹¹ and the Purdue Pegboard.¹² Numerous investigations with tests of this sort show their effectiveness in placing operators on jobs such as assembly, packing, and the operation of simple machines where the work is essentially repetitive and requires a minimum of understanding of the mechanical principles of the machine by the operator.¹³

Trade Tests. Frequently applicants for a certain type of skilled job have had (or claim to have had) previous experience which presumably qualifies them for the job in question. Thus an applicant for a stenographic job is supposed to possess a certain level of skill in typing; a tool maker, certain skills in the operation of machine tools; and an electrician, certain skills in this trade. Standardized trade tests in these, and many other areas, are available.¹⁴

Personality and Interest Tests. Numerous studies, such as one reported by Hunt,¹⁵ show that personality factors, rather than lack of trade or technical skill, very often prevent a man from getting along well on his job. The experience of personnel men also emphasizes the importance of personality factors in successful job performance.

To meet the need of appraising personality characteristics of applicants by test procedures, a number of personality tests have been developed. These include such tests as the Bernreuter Personality Inventory,¹⁶ the Humm-Wadsworth Temperament Scale,¹⁷ and the Guilford-Martin Personnel Inventory I.¹⁸

These tests variously measure several aspects of personality, such as introversion, extroversion, objectivity, dominance, agreeableness and cooperation. In the case of the Humm-Wadsworth Scale, several tendencies formulated around psychiatric concepts are measured.

The proper use and interpretation of personality tests require considerable skill and experience. Usually the pattern of personality characteristics revealed by the test is more meaningful than any single trait by itself. Also, personality test scores should usually be interpreted in conjunction with a mental alertness or intelligence test score. When used with proper precautions, personality tests frequently yield valuable information concerning applicants and employees.

Interest tests are also helpful in allocation of industrial employees and in vocational guidance. Among the more widely used tests in this field are the Strong Vocational Interest Blank¹⁹ and the Kuder Preference Record.²⁰ The former is intended primarily for use in vocational guidance of students who are choosing a career; the latter is also widely used for this purpose and is also used effectively in the placement of industrial and sales personnel.

Vision Tests. It has long been customary for industrial employment and medical departments

to give a vision test to new employees. This has been done both because it furnishes a medico-legal record in case compensation is sought by the employee for real or alleged injury to his vision, and also because of the recognized fact that many jobs calling for accurate and/or continuous visual observation cannot be adequately performed by persons whose vision is not satisfactory for the job.

The most commonly used industrial vision test has been the Snellen Chart,²¹ which contains letters of decreasing size which are read by the person being tested at a 20 foot testing distance. The test measures visual acuity or visual discrimination at this distance. Occasionally, but not frequently, the Snellen Test has been supplemented by a near point test.

Recent research has shown that the correlation between visual acuity at 20 feet and at 13 inches is far from perfect,²² and, in a few instances, a significant negative correlation between distance visual acuity and efficiency in performing a near point job has been found.²³ Certain visual skills in addition to visual acuity, either near or far, have also been found related to job success in numerous kinds of industrial jobs.²⁴

In order to make available to the industrial psychologist, the industrial personnel manager, and the industrial physician, a convenient and rapid means of measuring visual skills necessary for efficient job performance in various industrial jobs, the Bausch and Lomb Optical Company has recently made available a new vision testing instrument known as the Ortho-Rater. This instrument makes possible a factual determination of the pattern of visual skills required for each job or family of jobs so that by careful employee placement and adequate use of professional eye care every employee can be assured of adequate visual skills for the job he is hired to do.

Training Methods. Educational Psychology and the psychology of learning have revealed many principles which make learning more effective. This work has long formed the basis of instruction and preparation of instructional materials in elementary and secondary schools. Much, if not all, of the training given to industrial operators can make use of many of these same psychological principles of effective teaching and learning. Within the past few years industrial training departments have made a

greater and greater use of psychological principles in the operation of their training programs. Several specific studies dealing with this application of psychology are summarized by Lawshe.²⁵

Merit Rating. In every line organization men are judged or rated by the persons for whom they work. A recent survey has shown that at least a third of industrial plants have some type of formal rating system in operation.²⁶ These ratings often form the basis of transfers, promotions, and, in some instances, terminations. Psychology fully recognizes the possibility of errors in connection with ratings of this sort—errors such as the halo effect²⁷ which is the tendency to rate an individual either high or low in many traits because the rater knows (or thinks) the individual to be high or low in some specific or particular trait. This and other difficulties in merit rating can be markedly reduced by adherence to certain principles which have emerged from basic statistical studies of ratings.²⁸

Inspection. This is another area of industrial operation to which scientific psychological methods have made several specific contributions. Not only do tests assist in the selection of applicants for certain types of inspection jobs, but analyses of the job and an enumeration of the skills (visual and otherwise) required for adequate job performance often result in a job simplification in which more frequently found (or easily developed) skills may be substituted for rarer skills. Sometimes by changing the job itself, sometimes by more specific training of the inspectors, and sometimes by a more careful allocation of persons to the job—by these means quality of inspection can often be definitely improved.²⁹

Accidents and Safety. Numerous studies have shown that accident proneness is a significant cause of an appreciable percentage of industrial accidents.³⁰ Other studies have revealed at least some of the factors which tend to cause accident proneness.³¹ Recently a number of studies showing the relation between vision and industrial accidents have been published.³² Studies of this type not only aid in identifying some of the basic causes of industrial accidents but aid management and the safety director in initiating and operating a safety program which reduces those hazards that have been found due to personal factors within the worker.

Attitudes and Morale. How a worker feels about his job, his working conditions, and his company often determines how satisfied and effective an employee he becomes. The view, prevalent in some quarters, that money and wages are the only factors that cause employee dissatisfaction is not supported by the facts revealed by analysis of employee attitude surveys or union-management disputes. Morale surveys such as those reported by Hersey³³ and Wyatt, Langdon, and Stock³⁴ show that such factors as steady employment, fair adjustment of grievances, and receiving necessary help from management frequently are considered more important than wage increases by a majority of employees. It is also interesting to note that the majority of union-management dispute cases going before the National War Labor Board during World War II were concerned with matters other than money and wages.³⁵ Standard psychological methods of sampling employee opinion and feeling furnish management with a tool of real value in establishing and maintaining a program of sound industrial relations.

Industrial psychology is essentially the application of psychological methods to the solution of problems involving industrial personnel. Both management and labor organizations are recognizing the value of these methods in establishing a better understanding between management and labor and in settling controversies by objective methods rather than by arbitrary rule of thumb or decisions based on emotion rather than logical and carefully obtained facts.

INFANT PSYCHOLOGY. — The main problem of the psychology of infancy is to discover and describe how the behavior endowment of the newborn child develops during the first years of life. Its first task is to understand the elements and factors which constitute the cross section of behavior during the post natal period, and when this has been accomplished, to trace the transformations as they occur during the first two years of life. In a sense this broadly is the problem of the transformation

of the newborn human organism into a person. Unfortunately the problem of the infant's personality is the least studied datum in the field of infant psychology. It is evident that at birth the child is an individual organism but is hardly a personality in the accepted meaning of the term. The efforts of infant psychologists have been largely directed toward various conventional aspects of development such as emotional and social development, learning, speech, sensory and motor abilities, and mental testing.

The complexity of early development together with many gaps in knowledge of infant behavior are handicaps to an adequate coverage of the entire field. Moreover, the following treatment represents only one selection in the interest of brevity of the mass of data available.

SOCIAL REACTIONS

A very significant fact about the life of the newborn infant is that, while it is not a socialized being, it is one of the main foci of stimuli in the complex social environment of the home. The influences of this environment at first are directed upon the satisfaction of the child's physical needs and then increasingly it is bombarded with stimuli of strictly a personal or social nature. Gradually the child during its first years learns the habits of social living until it has adopted the culture patterns into which it has been born. The studies in this area of infant behavior have been directed not so much to the process of the socialization of the infant from birth but to the preliminary matter of recording behavior items which may be categorized as social. In listing possible items of social behavior the problem of adequate observational and experimental controls has not received adequate consideration.

Although the newborn infant is not a socialized creature, the two-year-old is an amazingly socialized person. Its social responses represent a process of differentiation and reintegration of uncoordinated responses which appear upon the background of its early chaotic and amorphous behavior. These patterns may conveniently be reviewed under three headings, responses to adults, responses to other infants, and responses to complex social situations.

The human adult is one of the first stimulating objects in the infant's environment and the face of the mother is a prominent aspect of

it. During the first days of life an infant may fixate the human face as it will fixate a light or any other object. These early fixations of course have no social significance until they become conditioned to a social situation. After six to eight weeks the baby will fixate the face quite frequently and often will smile. It is difficult to determine whether the first smiles in response to the face are due to the social situation or are induced merely by internal or gastric conditions in the infant. It has been found that at two months the baby will smile to the combined stimuli of the face and a clucking sound, that not until about five months will it react differently to a smiling and a cross face, and that at about seven months the child tends to reflect the assumed expression.

At an early age the infant begins to react to the mere presence of an adult. During the first quarter year of life it will usually follow the adult's movements but it also will follow the movements of any other physical object. Before the end of this period it will stretch out its arms, coo, and show increased body activity at the approach of the mother. Soon thereafter when the reaching and grasping patterns appear it may touch and manipulate the hand, arm, face, hair of the adult as it would any other objects. During the second quarter year activity and smiling are apt to be inhibited by the presence of strangers. By the sixth month infants jabber at adults. The social significance of all these activities is not clear.

It is known that newborn infants respond to some aspects of auditory stimuli. During the first two months the human voice has only a medium effect in relation to other auditory stimuli, although smiling has been found to occur in response to the voice. At this age a crying baby will cease crying at the sound of the voice. From about five to seven months an infant will cry in response to a cross or scolding voice. Although these responses are called forth by people there still is a question as to their social quality.

At about six months the infant will ordinarily cooperate with adults in such play as peek-a-boo, waving bye-bye, pat-a-cake. From eight to ten months raising and lowering of arms in imitation of adults is customary. Soon after a year the child will cooperate somewhat in dressing. Simple commands accompanied by gestures may be expected to be reacted to positively at about

a year, and to negative commands somewhat later. Negativism becomes prominent during the second year of life.

Infants at first do not respond to other infants. It has been observed that newborns in an obstetric nursery will all cry at about the same times in the twenty-four-hour period. It would be presumptuous to interpret this as a social reaction. Rather, the infants are hungry at about the same time and crying is a result of this internal state. When victrola records of crying are played the results have been found to be negative, the infants cry as frequently when the records are not played as when they are. It is reported that vocalizing in imitation of other infants appears from nine to ten months.

Aggressive behavior such as taking a toy from another, some resistance, hitting, hair pulling and biting for fun is evident toward the end of the first year, and is more prominent during the first half of the second year. Instances of affectionate and patronizing behavior toward younger infants have been reported at about the fifteenth month. During the first year of life children are unable to maintain contact with more than one individual at a time. Eighteen months is the earliest age at which group contact of three children has been reported.

It should be emphasized that the above description of infants' responses to other infants may not necessarily involve a true social situation. They may merely be responding to other infants as to any moving physical object placed before them. It is therefore difficult to determine to what degree infants respond to a complex social situation. It has been stated that a nine-month infant will cry if an adult pays attention to a nearby child. However it has been found that after two infants of this age have been together for a time and if the mother fondles her own baby and then picks up, fondles and talks to the other, the results are negative.

An interesting problem concerns the effect of different cultures upon the patterns of behavior of infants. The culture of a group determines the customary routine of the infant. Such matters as cradling, feeding routines, rewards and punishments have effects on infant behavior. Thus cradling on a board by a Hopi mother may accustom the child to certain sleep habits and the use of the breast may re-

duce the amount of crying. But the infant response patterns as such do not vary from culture to culture. Thus the Hopi or Navaho infant may not cry as much as White babies, but the cries are the same. Present evidence does not indicate that before one year of age there are any gross differences in infant behavior. A similar observation is made on racial differences of infants. During the second year of life the culture begins to condition infant behavior. Language is a case in point.

The study of the social reactions of infants needs further clarification such as will come with the use of more careful controls, the break-down of the general problem into easily handled experimental problems. Among these problems the first which should be attempted is perhaps the processes of learning by which the infant becomes socialized.

SPEECH DEVELOPMENT

One of the most striking processes of socialization during the period of infancy is the acquisition by the child of the language of his culture group. Speech, of course, is par excellence, an effective basis of social living.

The birth cry is usually a vowel sound, a nasalized *a* as in *sat* and represented in the International Phonetic Alphabet by the symbol [æ̃]. It may occasionally be varied so as to reproduce the sound *ε* as in *set*, or *ι* as in *hut*. Consonantal sounds also may appear but less frequently than vowels. The sounds *ng* and *ch* have been reported.

Thirteen investigations may be found in the literature of infant vocalization during the first month of life. It is convenient to list the sound elements used at this time under the three classifications of crying, whimpering, and non-crying, and to give them in the symbols of the International Phonetic Alphabet.

Crying

[i], [ε], [æ], [A], [ɔ], [ɪ], [h], [ʔ]

Whimpering

[i], [ɪ], [ε], [ε], [æ], [A], [k], [h], [ʔ]

Non-Crying

[i], [ɪ], [ε], [æ], [A], [u], [k], [ɪ], [h], [ʔ], [g]

About seven reports on the speech of six month-old infants are available. The following

speech elements are heard under the conditions of crying and non-crying.

VOWELS

Non-Crying

[i], [ɪ], [e], [ɛ], [æ], [A], [ɔ], [a], [ɔ], [o], [v], [u]

Crying

[i], [ɪ], [e], [ɛ], [æ], [A], [a], [ɔ], [u]

CONSONANTS

Non-Crying

[m], [n], [b], [g], [t], [k], [w], [l], [j], [θ], [h]

Crying

[m], [n], [b], [d], [k], [j], [h]

It is apparent that by the end of the second quarter of the first year of life infants produce most of the vowel elements and about half of the consonants. If the speech status of newborns and that of six month infants are compared a great expansion in the mastery of sounds is discovered.

At eighteen months the following individual sounds were heard in one sample of infants.

VOWELS

[i], [ɪ], [e], [ɛ], [æ], [A], [a], [θ], [ɔ], [o], [ɔ], [u]

CONSONANTS

[p], [b], [m], [w], [f], [v], [θ], [t], [d], [n], [j], [z], [S], [ʒ], [l], [r], [j], [ç], [x], [y], [k], [g], [h], [ʔ]

When vowels are classified according to front, middle and back infants at a year and a half show a distribution of 54 per cent front vowels, 15 per cent middle vowels, and 31 per cent back vowels. These values may be compared with the vowel distribution of adults which is: front vowels, 48 per cent; middle, 19 per cent; and back, 33 per cent. The two distributions are approximately the same. Thus at eighteen months a sample of infants may produce practically the whole vowel and consonant equipment needed in meaningful adult English speech, but may produce them in the same proportion before meaningful language has been achieved. The corresponding values for newborns are 85 per cent front vowels, 15 per cent for middle, and 0 per cent for back vowels. Thus it is seen that vowel development during infancy is largely the acquisition of back vowels

with a diminution of the production of front vowels.

It was stated above that all the vowels and consonantal sounds used in adult speech may be present at eighteen months of age. This statement is based on the sample of sounds used by 33 infants. No individual infant at this age had achieved the total adult phonetic equipment. However, when the mean number of phonemes of 100 infants from the first to the thirtieth month of life is plotted the resulting curve is a parabola. The mean number of elements present at the first month is 8 while at 30 months the mean is 27. The equation for the curve is $y = 7.5x^2$.

The literature yields comparisons of consonant production of infants during the second quarter year of life and the sixth quarter year. If consonants are classified according to the manner of articulation 2 per cent of such sounds are nasals in the early period and 10 per cent in the later period. Plosives amount to 29 per cent as against 48 per cent, semivowels respectively are 9 per cent and 11 per cent, and fricatives 60 per cent and 30 per cent. The changes in proportion of types of consonants according to the place of articulation between newborns and year and a half infants also is quite radical. The frequency of labials, dentals, post dentals, and palatal is practically zero for newborns. For the year and a half child the corresponding categories amount to 27, 1, 24, 4, and 10 per cent of consonants produced. At birth velars amount to 5 per cent, at the later age the amount is 10 per cent. At birth glottals are 95 per cent of the total consonantal production, at eighteen months it is 24 per cent.

Very little systematic study of the patterning of sounds has been attempted by workers during the first year of life. This period is a medley of vocalizations usually called babbling. During the first six months babbling is dominated by vowel sounds, increasingly during the second six months consonantal usage appears.

The first words appear at the end of the first year of life in the form of word approximations. The sentence appears somewhat later in the form of a one-word sentence. However, it is a sentence only in a functional sense, its structural differentiation into subject, predicate and modifiers being a product of late infancy. The ten most frequently used words in constructing the sentence are: "I," "is," "it," "you,"

"that," "do," "a," "this," "not," and "the." From two years the length of the sentence will increase from 1.7 words to 4.6 at five years. Nouns and verbs are used more frequently than adjectives and connectives. Declarative sentences predominate when the child masters the sentence form. The ability to express itself with reasonable clarity if not with complete maturity is evident normally at two years.

LEARNING

A number of investigations have been performed on the learning ability of the infant. Most of them have approached the problem by means of conditioning techniques.

Some of the responses of infants which have been conditioned are feeding or sucking, withdrawal of limbs, eyelid closing, fear and other emotional responses, and the psycho-galvanic response. Stimuli which have been used in these experiments include the sound of a bell or buzzer, an organ tone, colored lights, mild electric shocks, tactile stimuli such as tapping by a cutaneous vibrator, live objects such as rats and snakes, and also colored milk bottles and toys. The conventional procedures used in the conditioning of animals have been followed with infants. Departures from conventional techniques have been the introduction of experimental controls. These have been of two types, one in which a control period has been introduced in the individual infant's performance and a second in which a separate group of infants have been used. There is a tendency to treat results statistically as well as individually. Moreover, when non-instrumental recording, that is by an observer, is used, reliabilities of observation have been established.

Conditioning phenomena have been found present throughout the whole period of infancy including newborns. There is good evidence that simple conditioning may be established during the first week of life, that feeding reactions of the infant may be conditioned to the sound of a buzzer, that changes in feeding schedules may be conditioned, that on the fifth day eye-lid closure may be conditioned to tactile vibratory stimuli on the plantar surface of the foot, withdrawal or flexor twitches and respiratory gasp in response to a pure tone, and that withdrawal responses to visual stimuli may be set up on the sixth day. Anticipatory reactions have been observed during this period. It usually requires a

large number of pairings of stimuli to set up the response at this time. On the whole it may be stated that conditioning of newborn infants occurs but usually after many pairings of stimuli, and then only in a quite unstable manner.

During the second month of life and throughout the period of infancy conditioning becomes more easily established. Retention may last as much as from a few days to more than a month. Feeding responses to auditory stimuli may be set up during the second month. Clear differential conditioned responses, with an organ tone and an electric bell as stimuli to be differentiated were obtained between 110 and 122 days after birth. The infant of four months is able to differentiate a difference of five and a half tones. Conditioned reflexes in response to light are formed by the end of the second month. The first visual differentiation (colors) is formed in the fourth month of life. The Russian investigators incline to the view that the time of formation of auditory and visual conditioned responses does not depend as much on the number of pairings of stimuli as upon the age of the infant.

Among conditioning phenomena which have been observed with infants are: external inhibition, generalization, experimental extinction, internal inhibition, spontaneous recovery, inhibition of inhibition, differential conditioning, trace response, and higher order conditioning. One study has reported that when newborns are in a state of complete muscular quiescence the strength of response decreases and finally drops out. This would point to the existence of an optional amount of activity as a condition for successful results. It has been found that with continued pairings a high level of conditioning may drop to a somewhat lower level. Moreover when the infant is satiated it is difficult to successfully condition it. This indicates that contiguity is not the only factor for conditioning but that motivation likewise is a necessary factor in the process. It has been found that when an electrode is attached to the arm and electric shock is paired with the sound of a metronome the first responses are generalized so as to include the legs as well as the arms and that later the response becomes localized upon the stimulated arm. Anticipatory effects accompany the transition from the generalized to the local type of reaction. Thus infant conditioning processes show a stage of generaliza-

tion of responses as well as the stage of generalization of stimuli exhibited in animal work. Moreover there is evidence that other responses of the infant become conditioned at the time that the particular response in which the experimenter is interested is developed. The conditioning of these concomitant and associated responses would indicate that there are adaptive features present during early infancy. The conditioning process has been used experimentally both to induce fear of objects and to eliminate emotional responses in infants.

Curves of the rate of acquisition of the conditioned response are found to be S-shaped. This type of curve might be expected to hold for infant learning. The initial acceleration is probably due to the fact that the infant has no endowment of previous experience to bring to the learning situation. Interestingly, curves of the rate of decrement for successive experimental extinctions show a reversed S-shaped curve which is a mirror image of the curve for rate of acquisition. This is true for the first curve of a series of extinctions.

The instances of infant conditioning described above are concerned with laboratory procedures. Little work has been done in studying conditioning as it occurs during the actual process of socialization, that is, conditioning infants to the social and cultural environment into which they are born. Some beginnings, however, have been made with the infant in primitive cultures. A non-experimental attempt to describe the learning process of the Kwoma infant has been made. It consists in the application of a learning paradigm to a number of illustrations of the modification of infant behavior in the pre and post weaning periods. The paradigm is in terms of drive, response, cue, and reward. Some interesting observations of the modification of infant behavior in the Hopi and Navaho cultures also are available.

EMOTIONS

The problem of the emotional endowment of the newborn and its subsequent modifications and development has not yet been entirely clarified. This may be due in part to the absence of a clear-cut definition of emotion and in part to a lack of research.

According to Watson there is a group of emotional reactions which belong to the original

and fundamental nature of man. These reactions, designated as fear, rage, and love, are to be defined objectively in terms of situation and response. Fear responses consist in sudden catching of the breath, clutching randomly with the hands upon dropping, sudden closing of eyelids, puckering of lips and crying. The situations which arouse the fear pattern are dropping or loss of support, and loud sounds. There is no fear of darkness at birth. The rage pattern includes crying and screaming, body stiffening, slashing of hands and arms, drawing up and down of feet and legs, holding the breath and flushed face. This pattern is evoked by hampering the movements of the infant such as holding the arms tightly to the sides, clasping the elbow joint tightly between the fingers. Love connotes a broad meaning resembling approximately the sense of Freud's term *sex*. If the infant is crying, crying ceases, a smile may appear, gurgling and cooing are present. The smile and laugh are classed as original reaction tendencies. The situations in which love responses appear are stroking or manipulating an erogenous zone, tickling, shaking, gentle rocking, patting, turning upon stomach across attendant's knee.

It is to be noted that these three types of emotional reactions meet the criteria of emotions: a reaction pattern, a definite stimulus, no particular adjustment made to an object in the environment, responses which contain both skeletal and visceral elements.

This highly publicized view of the human being's original emotional endowment has been repeatedly challenged until now it finds little credence. The validity of Watson's account suffers from demonstrations that observers such as graduate students in psychology, nurses and medical students are unable to differentiate and name the emotions as exhibited in motion pictures or by direct observation of infants. When the observers were shown the responses but not the stimuli they showed more disagreement than agreement in their identification of the response patterns. Nine different emotions were reported for four responses. Hunger was judged as anger, fear, pain and hunger, and pain was judged as anger and fear, each about three times more frequently than pain. Anger likewise was judged as fear, pain, hunger and anger.

As a matter of fact other investigators have been unable to verify Watson's observations.

Several investigators have found that when the infant is severely hampered, he goes to sleep; another reports when an infant is suddenly raised in the air that the reaction is similar to that which appears upon being dropped. In this situation very little crying appears. It is concluded that the reaction is a labyrinthine response to acceleration in space and is not an emotional reaction. Slow-motion pictures reveal that a baby may be repeatedly dropped without inducing crying. Nor are loud revolver shots followed by fear and by crying in a majority of infants.

When Watson's experiments were repeated in an experiment meticulously using his own techniques, an analysis of the data revealed that responses were not significantly differentiated according to various situations. On the contrary the data failed to disclose any pattern responses corresponding exclusively to the four stimulating conditions employed.

Bridges has outlined an approach to the question of the primary emotions and their development during the period of infancy. This approach was based upon personal observations and the findings and theories of other workers. According to this view, there is one primary emotion to be identified as general excitement. A strong or sudden stimulus creates in the young infant at first a generalized disturbance. It is difficult in this situation to discriminate whether a baby is frightened, angry or pleasantly excited. As the child develops, excitement increasingly becomes differentiated into two general types of emotions. One of these may be called distress and perhaps should include what Watson called fear and rage; the other is delight and may be the same as that designated by Watson as love. This is a genetic theory assuming that there is an undifferentiated emotion becoming differentiated and associated with certain situations and motor responses to form the separate emotions which in turn become differentiated. Thus distress becomes modified into fear and anger, and delight into joy and affection. No specific assumptions are made regarding an exact time for the appearance of these reactions but by the end of the second year general excitement has become differentiated into fear, anger, distress, disgust, jealousy, excitement, delight, joy and affection.

It has been found by means of conditioning techniques that the infant's emotions may be

modified. A hospitalized child of eleven months named Albert was tested with a rat, a rabbit, a dog, a monkey, also with masks, cotton, and wool to determine whether fear responses were called out. In none of these tests did fear reactions appear. Then a rat was presented and a steel bar was struck with the hammer immediately behind the child's head. The procedure was repeated and subsequently other objects were shown with reinforcement. Marked fear and flight reaction, puckered lips, trembling and crying were successfully conditioned.

That fears may be eliminated was demonstrated by the case of Peter, who was afraid of furry animals such as the rabbit, the rat, fur coats and of feathers. By associating a pleasant stimulus, candy, with a negative one, a rabbit, the fear pattern became unconditioned.

Emotional responses in infants are not correlated to any specific stimuli but rather to certain specific aspects of stimuli effective in evoking response patterns. These specific aspects are intensity, duration of the stimulus and suddenness of presentation. Most workers now hold that in the neonate there are no specific response patterns. It is customary to use crying as an index of emotionality but crying may appear in conjunction with generalized behavior and seldom by itself. Smiling has been studied in reference to the pleasant emotions. Most workers agree that it appears at about the age of two months and laughter appears later. Little can be said about the visceral components of the infant's emotional reactions and since language is absent nothing about the subjective aspects of the problem is available.

The problem of the emotions of infants, then, is not in a very satisfactory state. The criteria must be in terms of objective patterns and the stimuli which elude them, and this has not yet been completely worked out. It seems probable that further exploitation of Bridges' approach to emotional development may lead to a better understanding of how these behavior patterns develop.

MENTAL DEVELOPMENT

A number of tests and scales have been devised for the purpose of measuring the development of the infant. Among the more prominent ones are those by the following: Gesell, Buchler, Bayley, Kuhlman, Linfert and Hierholzer, Fillmore, Cattell.

The purpose of these efforts has been to measure the development of the child during the first two or two and a half years of life in order that (1) an estimate of its developmental status at a given time may be made, and (2) its future mental status may be predicted.

The Gesell schedules of development represent the most comprehensive attempt to inventory behavior items during the period of infancy. The specific behavior items were collected at the Yale Psycho Clinic and grouped into four categories: (1) motor, items which relate to muscular capacity and coordination; (2) language, items which include vocalization, speech, and auditory comprehension; (3) personal-social, items which involve social experience and personality traits; and (4) adaptive behavior, items which concern ability to exploit the environment and imposed situations.

These normative schedules are clinical instruments; they are not standardized tests. For their clinical purposes they are extremely important. Moreover, they are the main source of behavior items from which more recent tests have been constructed.

Another prominent attempt to measure infant development is by Bühler. Her tests are samplings of behavior from four main lines of action: (1) bodily control, (2) mental ability, (3) social development, (4) manipulation of objects. Although the behavior items are similar to those of the Gesell schedules a much more systematic attempt was made in the construction of the test. It is intended to give a cross-section of the child's personality at each stage of development. The results are expressed in developmental quotients which may be presented in a profile which shows the relative development in sense reception, bodily control, manipulation, learning, social reactions, and mental production. The items were placed at a point where 66 per cent of the infants succeeded.

Quite early Kuhlman attempted to extend the Binet scales to the three-month age. This is a standardized test and considerable thought and practice have gone into Kuhlman's work. He has subjected his tests to a number of revisions. Items were placed at a level at which 50 per cent of the children passed. The scores may be read either as mental units on the Heine curve of mental growth or as intelligence quotients.

The Linfert-Hierholzer scale consists of two

parts, one for infants of one, two and four months, the other for infants between six and twelve months. It is not divided into age group tests; accordingly a six months infant is given all the tests in the second series, and so on.

The most recent and what promises to be perhaps the most useful instrument for measuring the development of infants is the Cattell tests of intelligence which include tests for each month from the second to the twelfth months and tests on the even months from the fourteenth to the thirtieth months. This scale is integrated with the low end of Form L of the Stanford-Binet scale. Included in each month's lists of items are a group of alternate items which make it an adequate scale so far as numbers of items is concerned.

Other scales which may be mentioned have been constructed by Fillmore, Bayley, Richards, Shirley, Shotwell and Gilliland.

There is the problem as to whether these items are really tests of intelligence of infants or tests of general development during the first two years of life. It is indeed a question as to whether young infants exhibit intelligent behavior at all. A conservative view is that these instruments as fashioned at present do not possess reliable predictive ability and yield merely estimates of developmental status.

SENSORY ABILITIES

Vision. The eye of the newborn is a somewhat different sense organ than that of the adult. Throughout the early months of life it continues to undergo changes in shape and growth. The cornea and lens become less curved, the length of the eyeball increases in relation to width, rods and cones in the retina increase tremendously in number, the former becoming deeper and better placed. Papillary action is slower than in adults and the external muscles are not too well coordinated. The optic nerve at first is not completely myelinated, nor are the connections from the visual centers of the midbrain to the visual cortical areas mature at birth. However, visual purple is known to be present in the retinas of prematurely born infants. There is general agreement among investigators that newborn infants respond to visual stimulation. The main problem concerns the determination of the kinds and degrees of discrimination present.

Young infants respond to lights of varying

intensity. The pupillary response is a function of intensity and increases in rate with age. The palpebral response and head retraction are elicited by a sudden onset of light and there also are changes in respiration and circulation. The Moro reflex may be evoked by a sudden strong light. Convergence of the eyes resulting in fixation has been observed in newborns but strabismus continues into the second month. Another criterion of the effect of light is the amount of body activity present under varying intensities. It has been found in a series of experiments that as intensities vary from .002 foot candles to 50 foot candles there is increased inhibition of activity. It has been demonstrated that the sensitivity of the infant eye is increased by dark adaptation.

Pursuit movements of head and eyes to a slowly moving light may be observed during the neonatal period. When a rotating visual field was used to evoke pursuit movements, they were found to be increasingly present after the second week of life. In this situation optic nystagmus was observed a few hours after birth. Response to the horizontal and vertical movement of a ring is placed in a scale of mental development at two months. The same test places the following of a ring in circular movement at three months and of a ball rolled across the table at four months. Visual acuity is a factor in pursuit movements and thus is indicated in the previous remarks, although the fineness of this ability has not been demonstrated in young infants. The effect of flicker has not been systematically studied in infants.

Some work has been done on the ability of infants to discriminate form. It has been found that a fifteen-month infant can learn to discriminate between a triangle and a circle, and between a cross and a square. Form board discrimination has been demonstrated in children under two years of age by means of a conditioning technique. The forms were blocks in the shape of a lozenge, a square, a circle and a maltese cross. The reward was a cookie placed under the block.

The appearance of the phenomenon of size constancy has been investigated in terms of the infant's differential reacting movements. It was found that six-month infants begin to reach for objects according to their actual rather than their retinal size.

There is disagreement among investigators

concerning the degree of ability of newborns under ten days of life to discriminate the various hues. There is evidence, however, that they respond differentially in amount of body activity under lights at the two ends of the spectrum. Blue has been found to have a greater effect in inhibiting body activity and crying than red or green light. The effect of red light is not much different than the influence of darkness. If the inhibiting effect of blue is taken as 100, then green light has a relative brightness value of 60, and red of 46. Girls seem to be better discriminators than boys. Whether the Purkinje phenomenon is present is a controversial matter.

The conditioning method has been used to approach the problem of color vision in the early months of life. Yellow and red electric bulbs have been each paired with a bottle of milk as the unconditioned stimulus. The age of six subjects at the beginning of one experiment ranged from two weeks to a month and a half. Interestingly, the age at the formation of the simple conditioned response to colored light for the youngest and the oldest infant was the same, one month and twenty-nine days. The youngest child required 200 pairings to establish the response, and the oldest only 49. This suggests that age is an important factor in establishing simple conditioned responses to hue during early infancy. Differentiation between green and yellow, and green and red was not established until the fourth month of life.

Another method employed in investigating the hue sensitivity of infants consists in observing eye movements in response to a spot of colored light which is moved across a gray area of the same brightness as the colored spot. Infants up to seventy days showed pursuit movements in from 90 to 100 per cent of the presentations.

A preference method has also been used successfully with infants under two years. Subjects from two to five months differentiate colored from colorless light, and those from five to twenty-four months, in addition, show a greater preference for red and yellow over gray than for green and red over gray. When red-yellow, red-green, red-blue, yellow-green, yellow-blue, and green-blue were equated for brightness and presented to infants ranging in age from six to twenty-four months, the preferences were in the order of red, yellow, blue, and green.

Two-year infants are able to match colors

with an accuracy of 45 per cent, and to name colors with an accuracy of 25 per cent.

Audition. The problem of the auditory sensitivity of the newborn infant has been subject to a considerable amount of controversy. The reasons for doubting the existence of this ability revolve about the following matters: the tympanic membrane is at an angle at which sound vibrations are inadequately effective, the external meatus of the ear is filled with glandular secretions, the ossicles are too rigid for functioning, the auditory nerve is imperfectly developed. The view most generally held at present, however, is that the infant does hear at least within a few days after birth. There is an accumulation of evidence in support of this position.

The problems of audition may be considered under several headings: intensity, duration, pitch, complexity, noise and pure tones, discontinuous sounds. The systematic exploitation of the auditory capacities of infants has had little application of scientific controls, adequate calibration of stimuli and of instrumental recording until recently. It has long been known that young infants respond to loud sudden noises by means of the body jerk or startle. A considerable array of noise stimuli have been used to elicit reactions. They include a pistol shot, the banging of doors, a hammer striking a metal bar or tin can, the rustling of paper, wooden snappers, whistling sounds, an adult's voice, hand clapping, etc. Criteria of auditory response include the Moro reflex, eye-blinking, pupillary dilation, respiratory gasp, disturbed respiration, the fontanelle response, crying, and the amount of body activity.

Although newborn infants respond to loud sudden noises, it has not been demonstrated that they discriminate pitches. Careful work employing tones of 128, 256, 1024, and 4096 cycles and stabilimeter recording found no discrimination in babies under ten days of age. When the problem of pitch discrimination was investigated by means of a conditioning procedure it was found that differential sucking reactions to tones two octaves apart could be established toward the end of the second month and the beginning of the third month. Little work has been done and consequently little is known about the ability of the young infants to respond to complex auditory stimuli.

The newborn responds to increases in the

intensity of sounds. It has been established that they discriminate large differences of intensities. Thus they respond differentially to intensities of 30 and 70 decibels, and to 30 and 85 decibels with frequency and duration controlled. Finer discriminations such as 30 and 50, 50 and 70, and 70 and 85 decibels are not reliably discriminated.

Newborn infants respond differentially to brief durations of sound when frequency and intensity are controlled. With increase of duration there is a higher per cent of response but the increment is a diminishing one. Thus there is an increase in response with durations varying from 1 to 3, to 5, to 15 seconds. On the other hand, when the durations of sounds are of a larger order such as five or six minutes, an inhibiting effect in body activity is produced.

Discontinuous, repeated auditory stimuli produce rapid decrements in circulatory and respiratory responses. A similar result has been found when the criterion was in terms of activity. The response decreases with successive repetitions of the stimuli and the amount of activity per stimulation decreases as their frequency is increased within a given period.

The reaction time of the body startle to a stimulus of 581 cycles, and a duration of .07" with a constant intensity is $.18" \pm .03$. The reaction time of the respiratory gasp to sound is $.09" \pm .03$.

In summary, the young infant is not deaf. His auditory discriminatory ability, however, is limited to intensity and time factors. It does not discriminate pitches probably until late infancy, nor are its differential responses to the complex character of sounds developed.

Taction. The horny layer of the skin of the newborn infant is thin, the dermis is very cellular, the elastic tissue of the skin is feebly developed. The subcutaneous cellular tissue is well formed and sebaceous and sweat glands are not yet fully developed. Pacini corpuscles are well developed. In adult epidermis a graded series of cutaneous organs ranging from highly capsulated Vater-Pacini cells to diffuse nerve endings are present. In the epidermis of newborns Pacini cells are found.

Areas upon the infant's body surface which have been stimulated include the face, the trunk, the limbs, especially the palmar and plantar surfaces, and external body cavities such as the mouth and the nose. A large variety of

stimulations have been employed. Some of these are pin pricks, punctiform and general pressure, deep pressures, electrotactile stimulation, stroking, warm and cold applications. For these purposes a number of instrumental stimulating devices have been used with infants. Aesthesiometers have been employed and thermal devices such as cylinders and capsules through which water at various temperatures may be passed. Electrodes and itch powders have also been used. Some of these instruments have been calibrated; others have been used only for gross observational purposes.

For criteria by which to judge the effectiveness of cutaneous stimulation workers have made use of such responses as movements of the head and limbs, flexion, extension, grasping, plantar reflexes, the amount of body activity, sucking and mouth movements, amount of crying, respiration, fontanelle pressure and the galvanic response.

There is evidence to show that the tongue of the newborn infant is highly sensitive to touch but that the lip and mucous membrane of the nose are the most sensitive of the cutaneous areas. The palmar and plantar areas also are quite sensitive to pressure. There is diminished responsiveness to punctiform pressure on the face from the mouth region across the cheek to the area in front of the ear. The breast, shoulders, abdomen and back are least sensitive surfaces of the body.

There is a very extensive literature on the effect of plantar stimulation. It has been asserted quite frequently that stimulation of the sole of the young infant's foot evokes the Babinski reflex. However, carefully conducted studies using a variety of pressures upon various parts of the plantar surface of infants from birth to four years indicates that great toe extension is not the only response which appears, nor is it the most typical one. There is first of all great difficulty in reaching general agreement as to what constitutes "typicalness" in view of the fact that many mixed types of responses are present. As the child grows older there emerges a more definite toe response, tending slightly at first to be of the extensor character and eventually, at from six to eighteen months, of flexor character as well. Gradually all reactivity appears to decrease until at four or five years it has become negligible, and the characteristic result of plantar stimulation is the elicitation of

no response whatever. Attention may be called to the fact that stimulation of the upper surface of the foot evokes the same types of movements of toe and foot as does that of stimulation of the plantar surface.

Differentiation of contact or light pressure from other types of stimulation such as thermal, pain, gustatory is difficult. Moreover, the criterion for distinguishing light and deep pressure is especially difficult. Consequently much of the work with tactile stimuli is confused because pressures begin to arouse deep sensitivity. It has been found that pressure upon the skin of the baby will arouse a defense reaction of the arms and it has been asserted that if the flesh of the infant's leg is "clamped" localizing movements in the other foot will occur. On the other hand it has been found that during the first two weeks there is no response to a commercial itch powder composed of small plant hairs although with age increased body activity takes place. During the first six months there is no localized scratching in response to this type of stimulation.

Palmar contact with a rod or a pencil has been studied. Deep pressure or proprioceptive effects of course are involved. It has been noted that the neonatal grasping reflex has two phases. One is closure to light pressure upon the palm, which disappears in the period from sixteen to twenty-four weeks, and gripping which disappears after twenty-four weeks. The strength of the young baby's grip has been stated in terms of the length of time it can suspend its weight by its hands. The time is said to vary from a few seconds to two and a half minutes. When a dynamometer was used to measure the strength of the grasp it was found that the maximum strength of the strongest subject was 2200 g.

The development of prehensile activities of infants has been systematically studied. It has been found that in reaching for an object such as a cube or pellet the earliest approach is a back-hand movement in which the hand sweeps out and forward; the next type of approach is a circuitous movement which appears in about twenty-four weeks. Finally a direct and vertical approach is made to grasp the object. Grasping at first is clawlike in which none of the digits predominate. Later a nipping pattern of thumb and forefinger appears which involves precise placement of the digit upon the object.

The presence of electrodermal effects in young infants has been demonstrated. Average skin

resistance (palmar) for adults is 23,600 ohms; for the neonate it is 273,000 ohms. However, another study showed that plantar and palmar resistance in newborns is in general only slightly higher than in adults. Increase in skin resistance in infants is related to muscular reaction and decrease is related to increased phasic and tonic muscular activities. Skin resistance cannot be used, as is sometimes thought, as a criterion of sleep in infants. Latent times of the respiratory gasp and leg withdrawal to electric shock have been found to be highly variable.

There is disagreement as to the degree of sensitivity of newborns to pain stimulation. This has probably been due to the fact that results with various cutaneous areas differ as well as to the fact that the problem has not been too systematically exploited. Pain sensitivity has been investigated by means of needle pricks, the criterion of which is usually a withdrawal response. Depth of penetration may or may not be controlled. A study which employed a single needle jab with one-sixteenth inch maximum penetration reports that arm areas are more sensitive than head areas and that leg areas are most sensitive. Another study using repeated needle jabs found that head areas are more sensitive than leg areas. Pain sensitivity increases with age. It has been found that an average of 6.5 needle jabs in head areas are required to evoke a response on the first day of life, while from thirty-six to forty hours after birth 1.7 jabs evoked the response, with one stimulation sufficing after forty-one hours. The sensitivity of leg areas increases with age. This is shown by the fact that from the fifth to the seventy-fifth hours the number of stimulations necessary to produce a response decreases from ten to two, while thereafter only one stimulation is necessary. The reaction time to a needle jab upon the volar surface of the arm ranges from 0.12 to 0.70 second. The reaction time to stimulation of the plantar surface of the foot has been reported to be about two seconds.

Infants react to cold and warmth. Limited areal but not punctiform stimulation has been employed as well as general environmental stimulation. Cold, applied by means of capsules to the forehead, results in prompt and vigorous changes in respiration and fontanelle pressure. When a temperature cylinder is used on the forehead over an area of 50 sq. mm. with an average temperature of 11°-12° C., infants re-

spond in 73 per cent of the stimulations. Water filled glass tubes applied to the cheeks at 15° C. were effective 96 per cent of the time, and at 45° C. in 89 per cent of the time. However, these temperatures when applied to palmar surfaces evoked no responses in 74 per cent of the stimulations. The application of the temperature cylinder to the inner surface of the knee induced reaction to 91 per cent of the stimulations. The plantar surface is very sensitive. It has been shown that 94 per cent of response to stimulation of this area follows stimuli of about 45° C., and 100 per cent follows those of about 15° C. The oral cavity of newborns is sensitive to thermal stimuli. Responses are elicited at temperatures from 8° to 53° C. Infants will respond with sucking movements to milk at various temperatures.

General body activity is negatively correlated with temperatures within a range of 74° to 88° F., although temperatures of greater range than this are known to have profound physiological effects. Comparisons of thermal effects of young and old infants are not available.

Taste. As in the case of odor, taste sensitivity is relatively undeveloped in the early post-natal period. It is doubtful that newborns can definitely discriminate the four qualities of sweet, sour, salt, and bitter.

Methods of stimulation are the use of applicator sticks, nipples, and special nursing bottles. Stimuli used are substances in solution such as salt, sugar, quinine, acid. Controls such as mother's milk, air, or distilled water have occasionally been employed. Temperature may or may not be controlled. Little has been done to explore the sensitivity of various mouth and tongue regions of the infant. As a rule application of the stimuli has been areal rather than punctiform. Responses which have been selected as criteria of the effectiveness of the stimuli include sucking, mimetic responses, rejection of the stimulating device, crying, general body activity, respiratory and circulatory effects.

There is little discrimination of taste stimuli by young infants. When the per cent of responses to distilled water is subtracted from the per cent of responses to each of the substances the differences have not been found to be significant. There are irregular respiratory and fontanelle reactions to sour and bitter but no evidence of a discriminatory nature. Sweet stimuli seem to calm the infant. Sucking re-

sponses to sugar increase with age and an increase of mimetic responses to salt, sour and bitter seem to become more evident as the infant grows older. Salt, sugar, citric acid, quinine and water stimulations by means of applicator sticks do not evoke significant differential responses, although quinine and citric acid seem to be somewhat more effective than salt and sugar. When sucking is used as a criterion, salt solution and mother's milk produce differences in response.

Odor. There is lack of agreement concerning the olfactory ability of the newborn child. The problem is further complicated by the probability that with strong stimuli pain is a factor in the response to odors. Thus it seems certain that infants react to stimuli such as acetic acid and ammonia but it is doubtful whether the reaction is to odor as such or to pain.

For stimulation, solutions saturated in various degrees of acetic acid, ammonia, oil of cloves, valerian, violets, asafoetida, citronella, turpentine, pyridine, lemon and others are used. In the better experiments pure air serves as a control. The solutions are drawn into a syringe, carried to the nostrils of the infant and released. Responses which serve as the criterion of the effect of these stimuli are turning the head from the stimulus, throwing back the head, sucking, amount of body activity, grimacing, crying, respiration, fontanelle pressure.

It is highly probable that odor sensitivity is the least developed of the newborn's sense modes. The work in this field, moreover, is characterized by a dearth of good experiments.

There are only a few workers who have attempted to compare reactions to odors with those to pure air. Few controls such as of room temperatures have been made. Only one study has attempted to relate odor reactions to stimuli organized on the principle of Herring's odor pyramid. Reactions to ammonia and acetic acid are more prominent than to other substances. Although most solutions will evoke responses the same kind of movements follow each stimulus. There are no conclusive results regarding age and sex differences. Differences in percentages of response may be due to the intensity factor. Nothing in the data supports or refutes Herring's sixfold classification of odors.

Posture. The workers in this field of infant reactions distinguish between body control of the baby during rest and during movement.

The reflexes on which body posture and equilibrium during reclining, standing, and sitting depend are called static or postural reflexes. Positional responses are grouped into standing and righting reflexes. They are tonic in nature. Sense organs involved in these responses are proprioceptive, pressure receptors of the skin, the eyes, and the otoliths. Kinetic responses follow upon active and passive movements of the body, and are mechanisms which readjust the body after displacement. They are phasic rather than tonic; they proceed with comparative rapidity. Upon their cessation the body is again controlled by the static reflexes. The receptor organs involved are the semicircular canals. Some of these reactions have been studied in young infants.

The technique of stimulation in the case of the static or tonic responses includes rotating the head, bowing the head ventrally, head rotation with the chest either held or free, rotation of the pelvis with the chest either held or free, and inverted suspension. Kinetic reactions are evoked either by direct shaking of the head or by indirect head shaking as in tipping the infant and lifting him. In addition compounded stimulation of labyrinthine, proprioceptive, and visual receptors have been studied.

One of the most striking of the static postures of infants is the tonic neck reflex acting on the limbs. If the head is rotated so that the face is directed to the right shoulder, the right arm and leg will extend and the left limbs will flex. This response, however, is not invariable, nor will it when present always be as clean-cut as the description implies, for it may be disturbed by phasic or labyrinthine factors. It is present during the first three months of life. The Brudinski phenomenon is evoked in the supine position by ventral bending of the head. It consists in a drawing up and flexion of the legs. It has been reported as present during the first month but there is disagreement on this point.

Opisthotonos is another striking static posture in normal healthy infants. This reaction may be observed during the first half year of life. It can be evoked by grasping the infant above the knees and suspending it in an inverted position. During the first ten days momentarily maintained backward bending of the head occurs. Tonic flexion is the dominant posture of the arms. During the first quarter year

of life the reaction becomes more pronounced. During the second quarter year the most characteristic aspect is that the bending includes the lumbar region of the vertebral axis, but now the arms frequently go into a tonic forward extension. There is little struggling or crying during the first six months. Opisthotonos disappears about the seventh month and is replaced by forward bending at the waist and neck and is accompanied by crying. This unusual pattern is characteristic of normal infants and probably involves both proprioceptive and labyrinthine factors.

There is a tonic neck reflex acting on the trunk. If the infant is placed on its back and the head rotated to the side, the whole body follows the rotation. But if the thorax is held fixed, the pelvis will move in the opposite direction. This effect has been observed throughout the first year and for two and one-half years in 'idiots. If the thorax is held while the pelvis is rotated, the head will make a compensatory movement. This reaction is much less frequent.

In young infants held in a sitting posture a sudden flash of light is responded to by a backward jerk of the head, a posture which is maintained as long as the light continues.

If an infant is suspended in the supine position its body assumes a crescent shape with the head and legs up and the arms raised sidewise about horizontally with palms down. If now the head is pushed down the pelvic muscles will relax and the legs will hang down. Both proprioceptive and labyrinthine influences play a part in these reactions.

The above are a few simple instances of the effect of proprioceptive stimulation involved in various body postures of infants.

MOTOR REACTIONS

In this summary it is impossible to describe in detail the total array of reflexes which have been observed in the motor equipment of babies. Many have been indicated in the body of this article. In concluding the treatment of the behavior of the infant, the development of the more complex motor patterns will be described.

The studies in the area of research may be classed as normative, in which the mean age and range of appearance of a given activity is stated, and experimental, in which a given pattern is studied in terms of experimental and

control groups or individuals. A very brief outline of a few motor activities follows.

At one month the child lifts the head, retains hold of a large ring; at two months it carries an object to the mouth and turns head and eyes to a moving object or light. At four months the head is held erect when the child is carried, closes its hand on a dangling ring and opposes thumb to other fingers. At six months it sits momentarily, reaches for an object, rolls over, and drinks from a cup. At nine months it sits alone, rises to a standing position with aid of a chair, creeps, walks with help, and waves bye-bye. At a year it may walk with frequent falls, unwrap paper from a small object, put cork in a bottle and accept a third cube. At fifteen months it walks fairly well but with a wide foot stance, marks with a pencil, takes objects from a box, and places several pegs in a board. At eighteen months it will throw a ball, scribble, climb stairs, drink from a glass, point to eyes, nose or ear. At two years it runs, imitates vertical and horizontal strokes with a pencil, nests small boxes, tries to make a circle, piles blocks and points out objects in a picture. These normative items do not exhaust its complete motor equipment, however.

These norms do not correlate highly with intelligence test scores in the post-infant period. Their utility for predictive purposes therefore is still in doubt.

The period of infancy is characterized by three patterns of locomotion: crawling, creeping and walking. Crawling is defined as progress with the abdomen resting upon the sustaining surface. Creeping is quadrupedal progress with the abdomen lifted from the surface. Walking is erect or bipedal locomotion. The literature is replete with studies concerning the mechanics of these modes of progress.

INTELLIGENCE TEST STANDARDIZATION.

I. INTRODUCTION AND HISTORY

When the labors of test construction are completed, an author is confronted with the aphorism ". . . that whatever the intrinsic merits of an intelligence scale, its diagnostic value must, to a large extent, depend on the degree to which the characteristics of the originally tested groups will approximate those of the general population to whom the tests will be subsequently administered."¹ What this adds up to in practice is whether the standardizing population is a random sampling of the population. The population of our nation is of such a diverse nature that a test to have national application must deal with, as fairly as possible, proletarian, suburbanite, and farmer, urban and rural, poor and rich, northerner, southerner, mechanic and banker, or illiterate and collegian. The history of test standardization is a growing awareness of these factors and their increasing incorporation into standardization procedure.

The father of mental testing, Binet, was the

first to stub his toe on this ubiquitous rock. His final scale—in collaboration with Simon in 1911, shortly before his untimely death—in the words of Terman was ". . . decidedly too easy in the lower ranges, and too difficult in the upper. As a result, the average child of five years was caused to test at not far from six years, the average child of twelve years not far from eleven."² Undoubtedly this was due to gross errors in selecting his population to conform to national standards. The criticism having been made, the author attempted to remedy the defect by extensive testing in a more controlled situation. Terman's 1916 revision was based on 1,000 children below the age of fourteen who were tested in a school of average communities which all or nearly all of the students attended, while the portions of the testing that were intended to measure individuals above fourteen were standardized on 30 business men, 150 migrating unemployed, 150 adolescent delinquents, and 50 high school students.

With the coming of World War I, psychological techniques were introduced into the U. S. Army to rapidly classify men. These resulted in the evolution of the famed Alpha and Beta Tests and the Army Performance Test. While the tests were standardized on large groups from the army population, plus feeble-minded and students in colleges, no attempt seems to have been made to assess this population in terms of the national standards. It is not surprising, therefore, that in the general draft population during 1917 and 1918, no less than 47.9 per cent were rated below C Average, and this in a group already sifted for mental defectives. The Army Performance Scale was standardized on 260 adults and was approximately as accurate. This was better, however, than the 1916 Stanford-Binet, which would have classified 34 per cent of the white draft—the flower of American manhood—below I. Q. 75, i.e., feeble-minded.

With the ending of the war, interest in the testing of children was again revived, while the Alpha and the Beta were adopted as standard adult tests throughout the country. Typical of the newer types of standardization was Goode-nough's, used with her Measurement of Intelligence by Drawing Test, in which a careful attempt was made to have the children used in standardization approximate what was considered to be age-grade standards for the nation;

although there existed no way in which these national standards could be ascertained and local figures had to be interpolated as an estimate. Considering the lack of information, the attempt was a distinct step forward, as the accompanying table illustrates (Table I). Meanwhile, other test authors disregarded standardiz-

ing populations almost entirely and based their norms upon statistical data derived from such methods as bisecting the regression lines when the Pearson r was calculated for a correlation between the new test and the 1916 Stanford Binet. An example of this type is the Revised Beta of Kellogg and Morton in 1930.

* The Goodenough Data are calculated from Goodenough, Florence L., *The Measurement of Intelligence by Drawings*, World Book Company, Chicago, 1926, p. 38, Table 2. The United States Census Data are discussed more fully in a succeeding table. In certain cases the data had to be combined into two grades. This is due to the peculiar form of the data as presented in the Goodenough statistics.

G = Goodenough Percentages

U.S. = U. S. Census Percentages for 1940.

While the internal construction of tests continued to be refined, little was done to improve the standardizing population until the two individual tests that are now predominant were issued: the 1937 Stanford-Binet and the Wechsler-Bellevue. It must be pointed out, however, that some movement in that direction was made by several pre-school tests. The Merrill-Palmer Scale of 1931 was standardized on 631 children representative of the *Detroit areas* which, while very accurate for that particular region, is certainly not representative of the population of the U. S.; while this same criticism can be leveled at the Minnesota Pre-School Test, standardized on data representative of the

city of Minneapolis. In the same connection it should be pointed out that such famous standards as Gesell's are strictly applicable to infants from homes of middle socio-economic status, with parents of northern European extraction.

The 1937 Stanford-Binet made a serious and concerted attempt to master the problem. Schools of average social status were selected in each community, and the communities were carefully chosen to compensate for such factors as age-grade relationship and socio-economic status of the parents. The pre-school children, and those out of school in the higher grade brackets, were also evaluated in the same way.

The 1930 Census was used to evaluate the socio-economic status with serious discrepancies in groups III and VII (Table II). The age-grade distribution could not be evaluated at that time since no national criterion was available, but Table III illustrates the comparison with the 1940 Census data. It must be noted that, al-

though the test purported to measure adult intelligence, no adults were used in standardization. With this test the principle of compensating for the gradual slowing up of intelligence during adolescence in contrast to the relentless march of chronological age is fully compensated.

IV. Farmers	15.3	14.9
V. Semi-Skilled Occupations, Minor Clerical Positions, and Minor Businesses	30.6	31.4
VI. Slightly Skilled Trades	11.3	9.4
VII. Day Laborers (urban and rural)	19.5	6.6

* Terman, Lewis M., and Merrill, Maud A., *Measuring Intelligence*, Houghton Mifflin Co., Boston, 1937, p. 14.

The Wechsler-Bellevue Test is divided into a youth scale and an adult scale, each of which was separately standardized. The adult scale was equated against the national population of the U. S. by using the broad occupational classes of the 1930 Census, substituting for the 20 per cent of this group that should have been employed in agriculture; bankers, bakers, and teamsters as equivalent. Similar substituting was used for other smaller classifications. Men seemed to be well covered, but 55 to 90 per cent of each female age group was composed of "not gainfully employed." The youth scale was based on the age-grade distribution of the New York City schools, which are contrasted with the standards for a similar white group from the U. S. Census in Table IV. As Table V illustrates, the means and S. D.'s of each age group had to be smoothed, some markedly, in order to achieve a usable curve of growth and decline in intelligence with increasing age. Wechsler's test, however, was the first to compensate

for declining performance with age, thus releasing the average adult from the limbo of subnormal intelligence into which all previous tests had consigned him.

The Lewisburg Beta was the first test to be standardized on the basis of the 1940 Census data, released in 1943. Standardized for adults, the validating population is "meticulously sampled and matched" to conform to the 1940 Census standards for white adults with the criteria of grade completed and socio-economic status. As a result of the use of these data, and the rigorous conformation of the standardizing population to it, the means and the S. D.'s of the five year age-groups from 20 to 54 were regular enough to preclude smoothing and are contrasted with the similar Wechsler-Bellevue data in Table VI and Graph I. The use of adult prisoners as the standardizing group, however, may conceivably have reintroduced a minor sampling error.

II. CRITERIA FOR A STANDARDIZING POPULATION

While most psychologists would agree that a test should be standardized on a representative population, the method of achieving it is another matter. What is sought after is not an absolutely identical population. It would not make any difference, for example, if hair and eye color varied, or the percentage of the left-handed was inaccurate. What then are the factors that merit evaluation in the standardizing population? Briefly they can be subsumed under the headings of: (1) Age; (2) Education; (3) Socio-Economic Status; (4) Sex Differences; (5) Racial and (6) Geographical and Political Distribution.

Of these factors age has long been perhaps the most perverse. As obvious as it seems, one of the prime advantages of Binet's pioneering tests was the consideration of the child's age in rating him. While this was patent, it took 20 years of testing before the pattern was modified to include the fact that, beginning with *circa* age 12, the annual increment in intelligence becomes progressively smaller and smaller until maturity is achieved. This type of compensation was first begun by Porteus in 1933 and reached full fruition in the 1937 Stanford Binet. Shortly afterwards, the researches of Wechsler completed the full cycle by pointing out and circumscribing the principle of declining performance with age after maturity; beginning gradually at first, and then in an almost perfect linear relationship, at least to age 65, which is as far as research has penetrated.

Thus our population must have representative samplings of every age group to counterpoise the effect of waxing and waning performance as the individual grows, reaches maturity, and then deteriorates.

Age also becomes a factor when the limits of the group for which an M.A. or an I.Q. is calculated must be considered. This problem of choosing an interval can only be solved by using a general principle which will be applicable to all tests but which may also produce different results with each measuring instrument. The 1937 Stanford Binet, for example, progresses in terms of one month intervals from age 2 to 16. Thus a person's chronological age is rated in years and months. The Wechsler-Bellevue, on the other hand, uses three month intervals from age 10 to 15, one year intervals from 15 to 16, two year intervals from 16 to 20, and five year intervals after 20 years of age. In each case it seems that an interval was chosen that would provide that the I.Q. would advance at the rate of one or two rating points as the mental age increases month by month, or as the chronological age decreases month by month; while in the Wechsler-Bellevue the same occurs with the weighted score and age, although the method of computing an I.Q. differs. This division of the chronological age may very well differ from test to test although the results will in most cases be comparable.

Education should be evaluated in its broadest sense, but unfortunately there seems to be no yardstick for such an intangible, and for *group*

GRAPH 1
VARIATION in S.D. of WECHSLER and BETA STANDARD DEVIATIONS
 (See Table XX)

measurement school accomplishment in terms of age-grade distribution for all seems to be an accurate delineator. As a yardstick to measure cultural differences between groups it seems to be a sensitive instrument, *i.e.*, the difference between the median achieved grade of a white group and a Negro group is almost exactly proportional to the means of accomplishment of an intelligence test. The chief difficulty in the past has been the paucity of authentic data, but this has disappeared with the publication of Volume IV of the 1940 U. S. Census.

Like education, socio-economic status is a complex factor which, while it may be best

described adjectively, must be expressed as a factor in terms of something that can be evaluated statistically. If a discriminate employment rating is utilized, one that will differentiate horizontally by cutting through artificial barriers to form natural groupings, this ideal can be achieved. While there is still room for improvement, this has been executed by the editors of the 1940 Census who, for the first time, made available groupings, not according to industry, but differentiated according to actual level of the specific job; disregarding in most cases the traditional formalized differences. Thus laborers, whether they work in a ditch, a factory, or

on a ship, are classified together, while the factory manager, the skilled laborer, the semi-skilled employee, the accountant and the filing clerk, although working in the same factory, are placed in their proper category. Again these data appear for the first time in the 1940 Census, Volume III, under the heading of *The Labor Force*.

Sex differences pose many a prolonged enigma to the psycho-metrician. Some sub-tests consistently favor the distaff side, while others give the male an advantage. There has been a current tendency to eliminate these genre of tests in favor of those that show only small differences between the sexes (the 1937 Stanford Binet, the Wechsler-Bellevue, etc.). Two courses seem open: (1) to eliminate discriminating tests; or (2) to construct separate norms for men and women.

If the first course is pursued the differences between the sexes will be so small as to be negligible in most age groups. There seems to be no significant difference between the educational accomplishments of white men and women in the U. S., although there is a marked disparity between Negro men and women in this respect. Whether this is true in the age group from 1 to 5 is as yet not evaluated. The great difference in maturity in favor of females makes it a problem for specific investigation.

It is the considered opinion of the author that the factors embraced under the topic of race are a misnomer. It is an incontrovertible fact that races differ in their performance on intelligence tests, but that does not make the difference due to innate abilities. It has long been known that groups differing in opportunity for cultural advantages are not comparable. There is no reason to suppose that this does not hold true for inter-racial groups. Where this difference is of great magnitude, it is obvious; where it involves the comparison of average white population with a 9th grade education and a Negro group with a 6th grade education (the product of cultural deprivation), it is just as obvious if correctly evaluated. The same facts apply to a French-Canadian, an immigrant from the more backward countries of Europe, or an American Indian.

Distribution as to geographic and political areas is invaluable as a correcting factor for qualitative differentiations in our other factors.

For example, there are many different standards of attainment for the same grade in different areas. A group completing the eighth grade in California or New York has a distinct though imponderable advantage over a similar group completing the eighth grade in Louisiana or South Carolina. Similarly with socio-economic status. An average operator in a southern cotton mill, although plying an identical trade with one in New England, could show enormous differences in education, opportunities for cultural advancement, and even in salary and social position. The same problems exist in comparing a rural with an urban group in debilitating as contrasted with stimulating climates. Therefore, a proper balance as to geographic and political areas will be essential to the exact matching of the population.

III. THE NATURAL DIVISIONS INTO WHICH THE AGES OF INDIVIDUALS FALL FOR TEST STANDARDIZATION PURPOSES

The various ages, for conflicting reasons, cannot be evaluated for standardization purposes in the same manner. Roughly, they would fall into the four classes of: (1) pre-school children; (2) school children; (3) youths; and (4) adults.

Pre-school children must be set apart, but they have in no way tended to classify themselves on a personal basis. They have obviously neither attended school nor have a socio-economic ranking of their own. Therefore, they must be evaluated by a policy of indirection; through their parents. Since data on socio-economic standards are more completely covered for males than females, the use of the male parent alone will not only simplify the standardization but increase its accuracy. The other factors of age, sex difference, race, and geographic and political distribution are just as obviously available directly, and are to be found in the census data, as will be elaborated in its proper place.

School children (5-14), provided that the factors of age, sex, and geographic and political distribution are held constant, will be mainly differentiated by the national standards of age-grade distribution of children in school with socio-economic standards as a correcting factor should the sampling deviate significantly from the national standards for the main parent. Minor deviations will, in all probability, be of

minimal importance, especially if the first named factors are rigidly adhered to.

Youths (15-19), too, must have the standards of age, sex, and geographic and political distribution held constant, but in this age group we must divide the population into two categories which will be standardized separately before they are combined for the ultimate standardization, since the group is sharply divided into those who attend school and those who do not. The individuals who are attending school will be evaluated on the same basis as school children. Those who have left school can now be evaluated by their attainment in school (last school grade completed), and their socio-economic status is evaluated by the positions they hold, although this is less accurate than later in life when more sifting has taken place to assign work of more or less suitable nature in regard to the basic abilities of the individual.

Keeping constant the basic considerations already mentioned, the treatment of adults is based primarily upon the last school grade completed, while this is corrected by further manipulation to assure constancy with the socio-economic status of the nation, and at the same time holding education unvaried. It should be pointed out that the corrector for socio-economic status is much more valid when applied to males than females. This is due to the fact that the percentage of males in the labor force varies from 83 to 95 per cent for adults while in females it varies from 45 to 20 per cent, making discrimination difficult.

IV. THE DATA AVAILABLE TO FULFILL THE CRITERIA FOR EACH AGE GROUP

Since many of the factors are mutual to all age groups they will be discussed separately, while those that are distinctive to their particular age group will be treated under that heading.

Assuming that the test to be standardized consists of sub-tests which do not favor either sex, the standardization population should consist of *circa* 50 per cent males and 50 per cent females, although a slight advantage in favor of the males will bring it into a true relationship, particularly in the pre-school age. As there are but inconsequential differences between age-grade placement for males and females at all ages, the composite of the two is the one pre-

ferred. On the other hand, in such an item as socio-economic status, there are bound to be vast differences, and the sexes must be evaluated separately, then synthesized.

The United States is a nation with a large underprivileged minority, the Negro. This minority, as a whole, has a performance on intelligence inferior to whites. The inferiority seems to be proportional to the amount of cultural deprivation. To make the problem more complicated, the Negro, depending on his amount of cultural deprivation, differs significantly when northern and southern Negroes are compared. This is the problem.

The solution is at present still an uncut Gordian knot. It is true that all good tests today are based on a white standardizing population and therefore are unfair to Negroes as a national group; but northern Negroes, for example, are no more discriminated against than a large majority of southern whites; moreover, southern Negroes occupy a still lower rung on the ladder. Therefore the statistics encountered in this paper will be based on a white standardizing population, the product of which will be unfair to southern Negroes, and which must be compensated for by clinical means. One solution remains, but is still unexplored. In terms of culture the South is a depressed area as a whole. The solution may be found in a regional standardization for which ample materials are available in Volumes III and IV of the 1940 Census.

Proper and due consideration of geographical and political distribution of population fortunately offers a clear cut basis for classification. The data are divided in one section under the headings of urban, rural nonfarm, and rural farm population, and in the other the nation is divided into the broad politico-geographic subdivisions of North Eastern, North Central, Southern and Western areas. The data are presented in Table VII, with absolutes converted into percentages ready for use, and together with the median grade completed for whites.

Since socio-economic status has been discussed at length the table evaluating it is presented without further comment (Table VIII), except to point out the essential separation between males and females in this category.

The factors that will vary individually from the four age categories reduce themselves to two: (1) age and (2) education. Since they

must necessarily vary from category to category they are coupled in the discussion of the data for each group.

Since pre-school children are evaluated in terms of the male parent's education and socioeconomic status *q. v.* this will be postponed, but there still remains the pressing question of age in terms of how fine the graduations should be. While it will, of course, vary with the test, it should be desirable (and possible) to discrim-

inate in terms of one or, at most two months.

The education of school children, disregarding sex, is presented in Table IX and it is restricted to whites. In many cases very fine subdivisions have been introduced. While this may be too fine a discrimination for some practical work, it can be modified if necessary. At the same time it provides the necessary data for the most detailed of subjects. It must be expressly noted that it represents the *last* school grade

completed, and that modification, such as has been done in the earlier tables of this paper, is necessary for comparative purposes. The census itself makes the assumption that an extremely large majority are in the grade directly above the one designated as completed. The age categories will most probably be separated by an interval of two or three months and should by now discriminate to at least one I.Q. point or its equivalent.

Youth statistics (white) regarding education are presented, as stated in two tables. Table X represents those who are still attending school while Table XI represents those who have left school for any reason whatsoever. As in the previous educational tables, they are expressed in terms of last school grade completed and should be treated accordingly. As we approach

maturity, processes of growth and maturation become more complete and are greatly but gradually decelerated. Therefore our discrimination in age will jump abruptly from three or four months to one or two year intervals to maintain the same standards of the equivalent of one I.Q. point gradation.

To complete our pyramid we provide the educational accomplishments of the adults of the nation (Table XII). All the cautions and provisos previously made also apply to these tables which are likewise restricted to whites. The sudden spurt in education in the last 12 years represents an unequalled increase and is a factor by no means to be disregarded in terms of education, sociology, and testing. Age groups, due to the at first almost minute "deterioration" in intelligence, are comparatively long (five

years) and fall in well with the divisions of the census.

V. STATISTICAL AND MATCHING PROCEDURES

Now that psychologists are able to avail themselves of the accurate information regarding the phases of test standardization, it would seem that the reliance on chance in which so many tests have placed their faith in whole or in part should be eliminated as much as possible. To do this it is necessary to test a much larger number of persons than will ultimately be used. From this much larger population, which can be termed the initial population, a selected population can be calculated which will fulfill, in the ways outlined, the requisite of representing faithfully the white population of the U. S.

The method itself is simply to equate the initial population for that category against the standards outlined. The item that least meets the criterion then becomes the central figure, and the others are cut to reduce them to a comparative percentage to the control figure. Then the initial population in that category is thrown into a distribution, and the tests to be subtracted are done so in the proportion of the initial population. Since education seems to be our most reliable single criterion, this will be our prototype, with the others used as secondary correcting paradigms. In many cases it will be found that the sampling itself will be so slight that correction will be unnecessary, but this can never be relied upon. The final norms will be a reflection of the meticulousness with which this procedure has been adhered to.

INTELLIGENCE TESTS AND TESTING.

—The history of the testing of mental functions during the past one hundred years epitomizes the change in psychology from a structural to a functional emphasis. When Fechner stated his logarithmic law he believed that he had established a mathematical relationship between the physical and the psychical world, between body and mind. For forty years after the enunciation of his law experimental psychology remained an unapplied science, and psychologists continued their interest in the fundamental issues as to the nature and structure of mind. Not until the turn of the century was there any considerable emphasis by psychologists upon the discrimination of differences between minds and the nature of the differentiae, in and for themselves. By this time Galton, in England, had shown the possibility of many types of physical and mental measurements; Cattell had laid the foundations of mental testing in the United States; and Binet, in France, was on the threshold of publishing his first scale for the measurement of mental ability.

The development of mental testing might have gone along the psychophysical lines laid down by Weber and Fechner and continued by Wundt; or it could have developed by way of Ebbinghaus, Oehrn and Binet towards the examination of more complex intellectual functions. That the development was mainly in the latter direction may have been due to the increasing need for discriminating devices in the

rapidly developing systems of mass education; it may have been aided by the sometimes close conjunction of physical anthropology and psychology; and it was doubtless stimulated by the work of Galton and Cattell, both of whom held the view that the measurement of individual differences was likely to be one of the most fertile fields in the new science of psychology.

Justification for the use of tests for the measurement of intelligence would be more convincing to some if a universally accepted definition of intelligence were available. There are those whose writings suggest postponement of intelligence testing until the nature of intelligence is known. Such a position is untenable. The psychologist is, in some respects, not much worse off in the field of measurement than the physicist. The latter would be hard put to give a complete description of the nature of electricity, yet can make measurements of its functions which are adequate in terms of the assumptions upon which they are based. Moreover, through his attempts to measure electricity, inadequate though they be in some respects, the physicist is probably closer to a statement about the nature of electricity than he would be had he refused to use the limited possibilities of measurement available to him.

Successful measurement in any field would depend upon happy accident unless some assumptive bases were used. Eight decades of scientific research have seen proposed a number of assumptions with respect to intelligence. Ebbinghaus suggested that "intellectual ability consists in the elaboration of a whole into its worth and meaning by means of combination, correction and completion of numerous kindred relationships." Meumann stated that intelligence is the "power of independent and creative elaboration of new products from the psychical material provided by the senses." Binet believed that intelligence was characterized by "the ability to select and maintain a definite psychic direction, by the ability to make adaptations leading to a desired end, and by the ability to criticize one's own behavior." Spearman regarded intelligence as the ability to educe relationships and correlations. In a symposium on intelligence in 1921 (31) a number of psychologists contributed their views on the nature of intelligence. Thorndike defined it as the power of making good responses; Terman considered an individual intelligent in proportion

as he is able to carry on abstract thinking; Colvin regarded intelligence as the ability to adjust to the environment; Pintner as the ability to adapt to relatively new situations; Woodrow as an acquiring capacity.

Some degree of confusion in the measurement of mental functions can be ascribed to the nominative use of the term "intelligence." Such usage is probably a legacy of "faculty" psychology; "intelligence" and "intellect" with "emotions," "perceptions," "ideas," "thoughts," etc., used in the nominative sense, are often regarded as entities rather than as functions. The quest after the ultimate nature of intelligence is a worthy scientific occupation; however, until success in this direction is achieved, it is pertinent to keep in mind the assumption that intelligence tests are measuring a functioning complex rather than a defined entity whose nature and structure are known. Such an assumption implies that some degree of intelligence is inferred by behavior under test conditions and not that intelligence is directly measured. For an assumption of this kind there is ample justification; in all metricized sciences use is made of inference in measurement. Temperature is inferred from the length of a column of mercury; air pressure from the height of a mercury column; electric current from the rotation of an armature; sugar in solution from the rotation of a beam of polarized light.

There is a common thread of meaning running through most of the definitions of intelligence. The power of independent and creative elaboration; the ability to make adaptations; the ability to handle abstractions; the capacity to adjust to the environment; these and similar abilities are a function of the individual's apprehension of relationships. The degree of success or failure, in every behavior response, will vary with the individual's ability to educe relationships, whether the latter be concrete or abstract. The measurement of intelligent behavior, then, will be dependent upon the individual's successes or failures in the eduction, the apprehension and the reconstruction of relationships. It should be clear that this is no definition of the nature of intelligence, but a description of its manifestations. In view of our present knowledge of intelligence such a description is justified; it is the outcome of a plausible inference that there is a relationship between intelligence—whatever that may eventually prove to be—

and behavior, and that what is regarded as intelligent behavior is the result of functioning intelligence.

Differences among individuals in their manipulation of environmental processes make comparisons possible. There could be developed, as the result of such comparisons a relative scale of mental ability. Units of measurement on such a scale would be relative, and not absolute. Since it is impossible to use all elements of behavior in a single test, or to measure all individuals in a defined population, the test constructor is faced with two problems: the selection of appropriate behavior items, and the sampling of a defined universe.

As early as 1890, Alfred Binet expressed the view that tests of intelligence should measure the more complex mental functions. In his first scale (1905) the items selected indicated his attempt to sample the behavior universe of children of his culture, and thus measure intelligence in whatever ways it was manifested. The items selected for this scale were simple, varied, and of such a nature that the answers depended upon general learning to be expected of all in the culture, and not upon any special training. Probably the most careful selection of items was that made for the New Revision of the Stanford-Binet Scale. Several thousands of items were considered, and selection was made eventually upon the bases of "(1) validity (2) ease and objectivity of scoring, and (3) various practical considerations such as time economy, interest to the subject, need for variety, etc." (23). It will be apparent from a study of the technique used by the authors of this test that the final selection of items in an intelligence test is dependent upon an analysis of the responses of the individuals in the standardizing group, and not upon the arbitrary judgment of the constructor.

If the intelligence test is to be used beyond the standardizing group the latter must be a sample typical of some defined population. "The fundamental requisite for adequate sampling is that each individual of the defined universe must have an equal chance of being drawn, and that once drawn no unit may be discarded without risk of bias" (17). Sampling for the purpose of test standardization will involve the selection of individuals by stratified sampling using bases known to be relevant to variations in intelligence. This would include age and sex

groups, urban and rural populations, geographical groups, socio-economic strata, nationality of descent, etc. It is important to remember that a sample typical of one defined universe may not be typical of any other; therefore a test standardized on a sample typical of one universe may not be used on an individual or sample from another universe unless it can be shown that the latter universe is in essential respects comparable to the former.

It has been argued that since intelligence has a biological basis, the distribution of intelligence should conform to a normal curve. There are, however, some biological characters which do not conform to a normal curve, and intelligence may be one of these. It should be remembered that the shape of any distribution is determined partly by units of measurement. Few test authors assume equality of units of measurements for their tests. In the Stanford-Binet Scale items were selected so as to ensure that the mental age of an age group equalled its chronological age. This scale does not pretend to measure in equal units; it is a scale showing the ability of the tested individual in comparison with other individuals in various age groups. The distribution of the intelligence quotients of the children of the standardizing group ($N = 2,970$) is very close to a normal curve (16); however, in view of the lack of equality of units, it would be unwise to infer that the underlying trait intelligence is normally distributed. Thorndike's distribution on the basis of equal units seems to dispose of this problem in favor of normalcy; but since his equal units were established by the use of normal curve functions he has merely demonstrated normalcy by assuming it in advance.

Age scales of the Binet type are individual tests; only one subject can be tested at one time; the process requires the services of a well-trained examiner; large scale testing is difficult; psychological factors, such as rapport and incentive, need careful control. On the other hand, by means of group tests, most of which are point scales, many subjects may be tested at one time; such tests require a minimum training on the part of the examiner; scoring is easy and objective. While the individual test has some disadvantages, it gives more accurate results than the group test when administered under standardized conditions by a competent person. Both types of test have their place in a testing pro-

gram. There are occasions, in educational, military and industrial classification, when to give individual tests would be a waste of time; while in most clinical examinations, for diagnostic purposes, measurement by individual tests is essential.

According to the type of material and the nature of the instructions, tests may be classified as verbal or non-verbal. Most of the Binet type tests, while predominately verbal, use non-verbal material, particularly for the lower age levels. The development of non-verbal tests has been of importance during the past twenty-five years. Non-verbal material includes geometrical designs, pictures, maze diagrams, blocks, models, beads, form boards, etc. Non-verbal tests are used in testing programs involving young children, the mentally immature, the deaf, persons of limited verbal ability or expression, and the language handicapped.

Since the publication of Binet's first scale in 1905 there have been developed intelligence scales, individual and group, which, in the light of the accumulated evidence, do measure intelligence in terms of a relative scale. Since all measuring devices, for the measurement of physical as well as mental functions, are subject to their errors of measurement, the values obtained by the use of intelligence tests are observed values, not true values. This does not constitute any serious drawback to the use of intelligence tests, since it is possible, by the use of statistical methods, to make a statement relative to the true value in terms of the observed value.

One of the reasons for the development of the early mental scales was the need for selecting from the school population those children who, because of low mental levels, could not be expected to profit educationally in the regular school situation. With the rapid growth of mass education during the past five decades it might have been expected that testing programs would have increased in importance in educational systems. Such an expectation has hardly been realized. True it is that there are many school systems, and many individuals occupied in educative processes, that have made use of the results of intelligence tests, both as selective and as diagnostic instruments. There are, however, many systems that have remained oblivious to the possibilities of mental testing; there are relatively large educational areas in which no psychological services are available either for

teachers or pupils. An analysis of the mental ages of 2,106 of the children who comprised the standardizing group of the New Revision of the Stanford-Binet Scale indicates the wide range of mental age in the elementary school grades (16). Whatever may be the solution to the problem of heterogeneity of class groups, and there has been rather more opinion than fact surrounding this problem, it cannot be denied that "a teacher confronted with the necessity of teaching *en masse* third-grade children ranging in mental age from six to twelve years, or sixth-grade children of mental ages from eight to sixteen years, must indeed be versatile if she is to provide learning situations appropriate for all" (16). In view of the representative nature of this relatively large sample there is reason to believe that the analysis draws a fairly true picture of school grading practice. Moreover, since it is known that intelligence testing is common practice in some of the areas from which the sample was drawn it seems likely that even where results are obtained they are, by some educational authorities, viewed with suspicion or ignored.

The success of the Army testing program in 1917, when tests were administered to more than 1,750,000 army recruits, was sufficient justification for the reestablishment of a testing program on a greatly enlarged scale at the outbreak of World War II. Although much of the test material is restricted, particularly in the areas of technical aptitude, reviews of the aspects of the program which have appeared in current journals have indicated some of the scope and success of the program. In industry, too, during the past few years, there has been increased interest in the predictive possibilities of test results in industry; it is not unlikely that the field of industrial personnel relations will, after the war, increase greatly the scope and usefulness of the psychometrician.

CHRONOLOGICAL OUTLINE OF MENTAL TESTING

INTERESTS.—The term is used to designate a concept pertaining to factors within an individual which attract him to or repel him from various objects, persons and activities within his environment. The concept is primarily an affective one. Its subjective expression, with emphasis upon the feeling component, is inferred through observations or behavior which can be interpreted as indicating liking or disliking, such as oral or written statements. Its objective expression, with emphasis upon the gross motor components, is inferred through observations of behavior which involve an approach to and a choice of alternatives which are equally available to the individual insofar as environmental barriers do not influence this choice. When a man says he likes the work of a journalist, his subjective interest in this vocation can be inferred. When he is presented with the choice of playing one of two equally demanding games, his choice of one of these games can be interpreted as objectively showing he has a greater immediate interest in that game. Therefore, an individual is said to be interested in an activity, person or object if he either expresses a liking for or makes a choice of that activity, person or object. These activities, persons and objects may be called "interest objects" insofar as the interest of the individual is directed toward them. The relativity of interests is demonstrated by the preferential hierarchy formed for each individual by these interest objects.

In defining interests, several criteria have been employed. The presence or absence of interests has been inferred when these criteria have been applied to the observed behavior. Attention and interest were regarded as synonymous by James Mill, and Henry James called attention the main criterion of interest. An individual was interested in the object or activity which held his attention. Attention wandered from that which did not interest the individual. If a child was to learn, he must pay attention in the classroom, and if he was to pay attention, his interest must be sustained. Herbart was the first to emphasize this interest factor in educational theory. If attention was shown, interest was present. Interest, however, is not the only factor determining attention.

Another criterion of interest, in more general use today, particularly in vocational guidance, and already mentioned, is a criterion based

upon the process of choice. In the presence of several alternatives, all equally available, the person will choose that alternative which most interests him. A person more interested in golf than in tennis will spend more time on the golf course than on the tennis court. Presented with a choice of two or more alternatives, an individual demonstrates an interest by making a choice of one of these. Again, interest is not the only factor influencing choice.

Another criterion of interest is persistence. A person will persist in an activity which interests him and will forsake an activity in which he has no interest. A boy who builds model planes for a few days and then puts away his kit and forgets about it is said no longer to be interested in model building. Very few people will voluntarily stay at a task which does not interest them, but as interests are not the sole influences acting upon persistence, some people spend a lifetime on a job which does not interest them. Here again the matter of choice enters in, for given a satisfactory alternative, the uninteresting behavior should not persist and the choice would be made in favor of the alternative.

Success has been employed as another criterion of interest. A child has been described as interested in the class in which he does successful work and that subject in which he receives his best grades has been called his most interesting subject. Interest in an occupation has been considered essential if a man is to be successful in that occupation and such success is said to be indicative of interest. Because success is so dependent upon factors of ability and opportunity, its presence or absence is considered a precarious criterion of interest.

Other criteria of interests have been used by various workers. Differential remembering has been used as indicative of relative interests. Presented with a variety of situations, the individual will tend to remember most about those situations in which he is interested. Learning has also served as a criterion of interest. The facts and behavior which are most easily learned are the most interesting. Positive relationships have been reported between vocational interest tests and information tests. Students with high scores on the physician's scale of the Strong Vocational Interest Blank, for instance, tend to have relatively high scores on the science and medicine sections of the Cooperative Contem-

porary Affairs Test, while those students with high interest scores on the lawyer's scale tend to have high scores on the other sections of the information test. The criteria involving learning and remembering are closely related to the criteria involving success and questions of ability and opportunity again complicate the direct application of these criteria.

Set, or predisposition, also serves as a criterion of interest. The individual will most probably respond to that situation which interests him most. The tendency to initiate a response toward a given interest object is similar to the tendency to direct attention toward that object.

Emotions, or feelings, as inferred from the individual's verbal or motor behavior, offer the most convenient criterion of interest. Asking a man in an interview or on a questionnaire blank is an economical and easy way of determining what he likes and what interests him. As the feeling component is essential in every definition of interest, the most generally accepted and widely employed criterion of interest is the feeling. The emphasis upon the feeling component is what demarcates the concept of interests from other concepts in the general field of motivation. When a feeling aroused by a stimulus is pleasant, an interest is said to be present. When the feeling is unpleasant, an aversion is present.

Interests have been classified in various ways upon the basis of the interest objects associated with the interests. A person responding to a vocation or occupation is showing a vocational or occupational interest. A person responding to a school subject is showing an educational interest, and a person responding to a recreational activity is showing a recreational interest. More specific classifications are often convenient. When a person's response is directed toward a machine, he is showing a mechanical interest. Depending upon the situation, this mechanical interest may be either a vocational interest, in relation to a job, an educational interest, in relation to a school shop course, or a recreational interest, in relation to a hobby involving machine work. The possible classifications of interest objects are numberless. Some of the classifications used include social interests, mechanical interests, intellectual interests, scientific interests, verbal or linguistic interests, literary interests, musical and artistic interests, clerical

and business interests, sales and persuasive interests, and mathematical interests.

The dimensions of interests considered in current research and theory include their duration, their extensivity and their intensity. Interests may be described in terms of how long they persist. Some interests are shown by almost everybody from a very early age to death. Some interests, equally persistent, appear in but a few individuals. Other interests, both those shown by many people and those shown by but a few, may endure for but a few hours. The permanence of interests is more striking than their transiency but many interests do endure for relatively brief periods of time.

The extensity of interests may be described in terms of the number of specific interest objects toward which the interest is directed. One man with predominantly mechanical interests may actually only show interest in typewriters but another man with mechanical interests may be interested in typewriters, automobiles, lathes and washing machines. Although both men possess mechanical interests, the latter can be described as showing the more extensive mechanical interest. In general, the more extensive is a man's *total* range of interests, the greater is the probability that he will make a healthy psychological adjustment to his environment, as psychoneurotic and inadequate individuals are characterized by their restricted ranges of interest.

The third dimension of interests is intensity. According to the criterion of interest employed, interests can be quantitatively ranked according to their intensity, or strength. When one alternative is chosen in preference to another, interest in the first is greater than in the second. When persistence is greater in one activity than in another, more interest is being shown in the first activity. Interests can be rated by individuals according to intensity. The intensity of an individual's interests can also be estimated by comparing his interests to those of other people whose interests are of a known intensity. This is most feasible with interest inventories, where the external referent has been most used in measuring the relative strength of interests.

FACTORS ASSOCIATED WITH INTERESTS

The interests of an individual are determined by a multitude of conditions, many of them

existing in early childhood or infancy. Some conditions, such as age, bear a direct influence upon interests. Other conditions, such as ability and educational factors, vary concomitantly with interests but the exact relationships between these conditions have not been ascertained. Genetic limitations determine what interests will develop but the variety of developments possible within these limitations is so wide that the early social conditions, familial, educational and recreational, are to be considered as the primary factors determining interests.

Insofar as an infant's attention is centered upon himself, he possesses no extrinsic interests and the existence of these interests cannot be inferred until the child is seen to respond to the objects and activities of his environment. The first few months of the infant's life show an increasing tendency to respond to the external world and by the third month the child is showing interest in certain restricted aspects of his environment. A little later, the child shows preferences for certain toys and persons and expresses aversions for those things which have obtained negative interest value for him. By the end of the first year the normal infant is quick to express interest both by his motor and verbal behavior.

The range of interests of the child changes as he becomes older, the greatest increase in this range occurring during the first few years. As the perceptual, cognitive and learning abilities of the child develop and as the variety of experiences to which he is exposed increases, his interests develop correspondingly. By the age of three years he is showing unmistakable interest in other children, in the adults around him and in the mechanical and biological events that surround him. The next years show an increasing interest in recreational and play activities and in vocational pursuits of the adult world.

Within given age groups, a community of interests is easily detected and the influence of tradition and custom upon these interests is obvious. Boys of a certain age and from a given economic and cultural background will tend to have interests in hobbies such as stamp collecting and model plane building. Other children of the same age but from a rural background will tend to show a greater interest in pets or hunting. Age norms for play inter-

ests of children have been developed by Terman, and Lehman and Witty.

Children in the early grades are most interested in subjects which permit bodily activity. At about the age of eleven, interest is to some extent transferred to subjects where perceptible results are obtained and where achievement is easily observed by the child. Later interests are centered upon the more utilitarian subjects, and school activities which appear most relevant to the future of the child become more interesting. Educators have discovered the futility of introducing subject matter to a child before his interest development has reached an appropriate stage. Under guidance, this interest development can be stimulated and directed, within limitations, as elementary teachers do when they attempt to bring the child to an adequate stage of reading readiness. The limitations mentioned are determined by the physiological, psychological and social maturation of the child.

The vocational interests of small children, as shown by their preferences, are characterized by their lack of realism. The child is attracted either to the occupation of the father or a favorite relative, or, in case that occupation is deficient in the excitement and variety demanded by the child, to colorful occupations such as fireman, railroad engineer, and more recently, aviator. The limited range of occupations preferred is demonstrated by comparing the 17,000 different titles included in the Dictionary of Occupational Titles to the one hundred or less preferred occupations that will be named by almost any group of children.

The vocational choices of individuals tend to become more realistic from junior high school through college, as the age of actual occupational embarkation approaches. When students seriously start to consider training requirements as compared to limitations of ability, their vocational choices tend to shift from the glamorous to the practical. That this shift is not characteristic of all individuals is evidenced by the discrepancy found between job opportunities available and the number of children and students planning to enter different occupations. For instance, although only seven per cent of all workers are in the professions, 18 per cent of one group of students choose these professions, and while 35 per cent of all workers are in unskilled jobs, only seven per cent of this group of students choose these jobs.

Vocational interests, as measured by interest inventories, show consistent and systematic changes with age. These changes can be described in terms of their masculinity-femininity, as measured by the Strong Vocational Interest Blank. Masculine interests, possessed by engineers, chemists, farmers, and physicists are directed toward mechanical occupations and activities and athletic and active recreations such as camping and hunting, while feminine interests, possessed by artists, lawyers and journalists, are directed to music, cultural activities and social welfare and linguistic occupations. The interests of boys tend to become more masculine during early adolescence and then gradually become more feminine. The interests of women become more feminine with increasing age.

Measured vocational interests reach a point of relative stability approximately at the time of physical and intellectual maturity and the general trend of interests can usually be clearly perceived as early as 14 years of age. Thus, if proper precautions are observed, the vocational interests of high school boys and girls are sufficiently stable to allow them to be used for guidance purposes. The stability of interests is shown by the correlations ranging from .74 to .90 between tests and retests given to a group of adults by Strong after an interval of one and one-half years. Follow-up studies after periods of five and ten years show the stability of vocational interests approaches that for measured abilities and intelligence. The more generalized the interest, the greater is the stability; the more specific the interest, the greater the probability of change.

As successively older groups of men at a relatively high economic level are studied, their interests tend to become more aesthetic, more cultural, less athletic and more feminine. However, interests, like many other attitudes, are well formed before the end of the second decade of life and after that time, in the typical adult, show little change.

The influence of sex upon interests has received as much attention as any other of the factors determining interests. During the first few years of life, the interests of boys and girls begin to be differentiated. Until early adolescence this differentiation is relatively slow and many children of one sex tend to show the interests that are commonly assumed characteristic of the other sex. During puberty and early

adolescence, endocrinological changes and emphasis upon social sexual patterns of behavior are accompanied by changes in interest, and as boys mature physiologically, they become more interested in girls, heterosexual recreations and clothes. These changes in interest appear more dependent upon physiological age than chronological age. Children failing to show these changes are considered personality deviates and the adult male whose interests are similar to those of the average woman is definitely a deviate.

The interests of many diagnosed male homosexuals have been shown by Terman and Miles to be more feminine than the interests of the average woman but many homosexuals do not have feminine interests and only a small proportion of men who have feminine interests are known to be homosexual.

The vocational interests of boys and girls differ widely, as shown by their occupational preferences. For example, in one study, 17 per cent of the boys graduating from high school wished to become engineers while only .1 per cent of the girls preferred this occupation. On the other hand, 19 per cent of the girls preferred teaching while only four per cent of the boys preferred this occupation. The differences in training and job opportunities for the sexes influence this difference in occupational preference, and evidence from Russia suggests that when these opportunities are equated, the occupational choices of boys and girls may become more similar.

The sex differences in measured vocational interests have already been mentioned. The vocational interests of junior and senior high school boys, as measured by the Strong Interest Blank, are similar to the interests of engineers, chemists, farmers, physicists, personnel managers and purchasing agents while the vocational interests of girls are more similar to the interests of architects, artists, lawyers, journalists, ministers and advertising men. Using the Kuder Preference Record, high school and college boys tend to obtain higher scores on the science, computational and persuasive scales and girls higher scores on the music, artistic, literary and social service scales.

To what extent these sex differences in interest can be attributed to biological and physiological factors and to what extent they result from social conditions is today unknown.

The ability of the individual is another factor bearing a possible influence upon his interests. One hypothesis, as yet unproven, is that a person's ability determines his successes and failures, and that success experiences foster the development of interests. Therefore a person's interests are indirectly a function of his ability. This hypothesis gained support from the results published in the 1920's which showed a correlation of about .80 between the interests a person judged himself to possess and the abilities he possessed, as determined by his own judgments. These results were not substantiated, however, when more objective estimates of interests and abilities were obtained.

These later results lead to the conclusion that interests and abilities appear to be independent variables; each one contributing its own quota to ultimate success. At best, interests are only slightly suggestive of ability. Between mechanical interests and mechanical abilities the correlations range from .15 to .35. The correlations between scores on 35 of the occupational scales of the Strong Vocational Interest Blank and the Thorndike Intelligence Examination for High School Graduates range from +.38 to -.33. Correlation ratios between six representative scales of the Interest Test and the factor scores of the Tests of Seven Primary Mental Abilities range from .04 to .31 with a median correlation ratio .09. Other studies involving the comparisons of groups with and without measured vocational interests reveal but few differences in abilities; and these differences rarely reach statistical significance. Interests as measured by other interest tests show a similarly small association with ability and intelligence.

The relationship between ability and vocational interests, as indicated by occupational choice, is perhaps greater than that between ability and measured interests but this relationship is still surprisingly small. In a study of 1500 junior and senior high school students, the median I.Q. of those students choosing a profession was 108; the median I.Q. of those choosing business or clerical work was 105; the median I.Q. of those choosing a skilled trade was 103; the median I.Q. of those choosing a semi-skilled trade was 102; and the median I.Q. of those choosing an unskilled trade was 100. No pupil with an I.Q. of between 120 and 150 selected a semi-skilled or an unskilled vocation.

So much overlapping existed between the vocational choices of the various ability groups, however, that in spite of the orderly progression of median I.Q.'s, the trends were not statistically significant. Another study of 2,700 high school students disclosed that the median I.Q. of the boys choosing the professions is but seven points higher than that of the boys who have chosen careers in the skilled trades.

Studies conducted at several colleges have shown that college students in various pre-professional and professional courses can be differentiated upon the basis of ability test patterns. This differentiation is of course in part a function of the standards and requirements established by the colleges. Students in law, medicine, journalism and engineering are usually found to have higher mean scores on scholastic aptitude tests than have students in physical education, agriculture, home economics and dentistry. The extent of overlapping is again so great, however, that the conclusion is warranted that intelligence, *per se*, does not always determine vocational choice. The higher the intelligence of the individual, the more likely he is to choose a profession and the lower the mental ability, the more likely he is to choose a vocation from the semi-skilled or unskilled groups. Ability, however, does not have a great influence upon interests.

CULTURAL DETERMINANTS OF INTERESTS

The age, maturational level, sex and physical status of the individual set the limits within which his interests will develop but the specific interests are determined by many cultural influences—national customs and traditions, home experiences and school room experiences. The exact determination of the relative effects of the various factors influencing interests is now impossible but systematic observation shows interests do vary concomitantly with many cultural factors.

The interests of a person are to a great extent formed by conditions in the family and home. If one set of conditions can be called the most influential in the determination of interests, this is perhaps it. The vocational interests of people, as shown by their chosen occupation, tend to be on the same occupational levels as the occupations of their fathers. The discrepancy between a child's occupational choice and his father's occupation narrows as the child ap-

proaches entrance to an occupation. Studies of occupational mobility show that in America, the occupational level of the family tends to remain constant from generation to generation. Traditionally, the occupational mobility in America is greater than it was in pre-war Europe.

In terms of specific occupations, the similarity between the vocational choice of the child and the occupation of the father is dependent upon the occupational level of the father. The sons of physicians are more apt to want to be physicians than are the sons of mechanics to be mechanics. The relationship between the vocational choice of an individual and the occupation of his father also has been found to be dependent upon the sex and abilities of the individuals concerned, the time of vocational choice and the method of determining this choice.

Studies using vocational interest tests given to children and parents and to twins suggest that the influence of the family upon interests is as great as its influence upon other personality characteristics. The sons of physicians tend to have vocational interests similar to those of physicians, as measured by the Strong Vocational Interest Blank. Sons whose fathers are in the skilled trades tend to have measured interests in scientific and technical occupations and sons whose fathers are in business tend to have measured vocational interests in business. Reported correlations between the measured interests of male college students and the measured interests of their fathers range from .00 to .48 with an average correlation coefficient of .33. In one study, rank difference correlations between the occupational scores of the individual father and son pairs ranged from $-.42$ to $+.95$, with a median at $+.66$. The same coefficients for unrelated pairs ranged from $-.56$ to $+.93$, with a median at $+.36$. Little doubt can be raised regarding the existence of a positive correlation between the measured vocational interests of the child and both the occupation and measured vocational interests of the father.

A relationship has also been demonstrated between the measured vocational interests of twins. In a study of 120 pairs of twins, Carter found a correlation of $+.50$ between the Strong test interest patterns of identical twins, a correlation of .30 between the interest patterns of like sex fraternal twins, and a correlation of .26

between the interests of unlike sex fraternal twins. These correlations are significantly lower than similar correlations involving physical and intellectual characteristics but they do resemble correlations found with other personality and attitude tests.

The familial resemblance of interests is a complex relationship. Factors determining a man's occupation involve both temperament and ability which are basic functions of the genetically determined physiological-psychological organism. On the other hand, the occupation of the family may produce an early atmosphere in which the child is reared and which in turn produces the same interests that are found in the parents, who originally determined the social structure of the home. Regardless of the sources of variation, the conclusion can be that the interests of an individual do vary according to his home and family.

The school is another potent factor determining interests. The teacher in nursery school and kindergarten is primarily concerned in arousing and maintaining the interests of the child and until such interest has been aroused, instruction in formal subject matter is futile. Specific techniques are available for accelerating reading interest, arithmetic interest and penmanship interest. The school is the only place in this society where a systematic and consistent attempt is made to form and direct interests and such attempts are, for the most part, limited to the first few years of a child's educational career.

Instructional techniques can, however, influence interests in older people, including those at the college level. Interest in laboratory courses can be sponsored to such a degree that students will voluntarily spend more time and expend more energy in those courses. Vocational interests can be also influenced in a desirable direction when adequate techniques are utilized. The extent to which vocational interests, as shown by occupational preferences, can be influenced depends upon both the amount and kind of occupational information and experience supplied to the student and the amount of individual time and the type of personal counseling made available to each student in the class. With appropriate classroom and counseling facilities, experimental studies have shown that vocational choices can be made more realistic and students can be influenced

to choose occupations in which their chances for success and satisfaction are greatest.

Children in school have been successfully differentiated upon the basis of their interests. Wyman was able to differentiate grade school children according to intellectual, social and activity interests. Hubbard was able to measure the mechanical interests of junior high school boys. Tyler has developed a test, the *Minnesota Interest Test for Girls*, which can be used in assigning high school girls to academic or commercial courses. Garretson's *Preference Questionnaire* can be used in assigning high school boys to academic, technical or commercial courses.

Attempts to measure the educational interests of college students have proved less successful. Tests are available which are of doubtful usefulness in assigning college students to courses in English, social science, natural science, foreign language, mathematics and education. During recent years endeavors to increase the efficiency of the prediction of school grades have been unprofitable and the development of educational interest tests may assist in raising multiple prediction coefficients.

Individuals differing on the basis of their interests have also been found to differ on the basis of other personality characteristics. The relationship between interests and sociability, emotional stability, radicalism, religiosity, and morale, although not high, is substantial enough to demonstrate the essential unity of the personality. College students interested in banking, dentistry, music and government, as shown by their vocational choices, are economically and politically conservative. Industrialists, bankers, and physicians who have attained observable occupational success, are among the most conservative of vocational groups. Students interested in journalism, law and social work tend to be economically and politically liberal. These liberal tendencies persist in adults who have been working in these fields several years. Students choosing business tend to be more optimistic, less cynical and less critically minded than other students.

Interests as measured by vocational interest tests also are related to other measured aspects of personality. People with interests in social welfare fields on the Strong test (teaching, social work, minister, etc.) tend to obtain high scores on tests of social adjustment, emotional

adjustment and extraversion. People with measured interests similar to those of engineers tend to have low scores on social adjustment scales. Students with measured interests in business tend to show themselves more conservative on various attitude scales, as compared to students who have measured interests in social welfare jobs. Finally, using the Strong Vocational Interest Blank, scales have been constructed providing scores which correlate from .21 to .52 with personality tests of self confidence, sociability, home adjustment, health adjustment and social adjustment.

Interests thus form an integral part of the personality, which suggests that major trends in interests cannot be influenced by relatively superficial experiences. Specific interests, directed toward isolated objects or activities, can perhaps be influenced by these experiences, but those factors determining the general interest patterns of a person form a complex of physiological, maturational and social conditions extending over a long period of time.

IDENTIFICATION OF INTERESTS

For purposes of guidance and research, interests are identified and evaluated in several ways. The first method used for research purposes, as exemplified by Thorndike's study published in 1921, and the most widely used method in guidance today, is one of simple interrogation. The subject is asked a direct question about what interests him. In vocational guidance the initial occupational choice is often used as a starting point in the determination of the subject's important vocational interests. Occupational preferences or choices, however, are very specific and may easily be changed by superficial experiences. Many times these changes are not congruent with the personality of the individual and a boy may not only choose an occupation for which he lacks adequate ability but he may also choose one for which he lacks appropriate interests. A student liking mechanical things and skillful in mathematics and the physical sciences may choose teaching as a profession because that is his father's occupation, whereas his chances of achieving success and satisfaction may be much greater in a field related to engineering. Because of the transiency of vocational choice and because of frequent disagreement with more fundamental personality structures, this expression of interest

can seldom be used alone and is useful only when evaluated in the light of other information.

The achievement record of the individual, as shown by test scores, successes and failures in school, on jobs, and with hobbies, offers another indication of interests. This is a fallible index, however, because success in every endeavor is due not only to interest but also to factors related to ability, training and available opportunities. Because of a fertile set of conditions, a man may achieve outstanding success while having little interest in what he is doing. Similarly, a person with great interest in an occupation may fail at it because the conditions surrounding him do not permit him to succeed. The mortality rates in universities and professional schools demonstrate that interest alone cannot produce success. Many students of mediocre ability show a genuine interest in becoming physicians but their limited abilities prevent them from even being admitted to a professional school, to say nothing of successfully completing the course of training. A boy interested in athletics may never make a school team because of inappropriate motor skills and physical development. For these reasons, interest can be regarded as only one of the many possible factors involved in success and failure and more is needed than this if interests are to be accurately identified.

Many psychological instruments have been devised or adapted to identify interests. Most attention has been paid to problems of vocational interest. The instruments used include word association tests (Wyman and Terman), differential information tests (Flannigan), learning and memory tests (Super) and interest inventories which obtain reactions to specific interest objects (Strong, Kuder, Cleeton, Thurstone). Most of the research has been done with the interest inventory type test and the most widely used interest inventory is the Strong Vocational Interest Blank.

Based upon the early work of Ream, Craig, Freyd, Miner and Cowdery, the Strong test, first published in 1926, has been developed by Professor Edward K. Strong, Jr., of Stanford University. The items of the test offer the subject an opportunity to express likes, dislikes and preferences for various occupations, amusements, recreations, activities, school subjects and personality characteristics. Separate forms of the

test are used for men and women. For the men's test, scoring keys are available for 38 occupations, and four non-occupational keys have been published. For the women's test, 18 occupational keys are available and one non-occupational key.

In developing the scale for a given occupation, the test is administered to a representative sample of successful men in that occupation. The percentage of people in that occupation who check a certain answer to an item is then compared to the percentage of people in the general population who check the same answer. For example, the first item of the test asks a person to check whether he likes, is indifferent to or dislikes the occupation of actor. Of all the 513 engineers given the test, 9 per cent answered they like the occupation of actor while of the general population, 21 per cent checked they liked it. In this case of the engineer's scale an answer of *like* is given a negative weight, the size of which is a function of the size of the difference found between the group of engineers and the general population. In this way three weights are found for each of the items and this is done for every scale to be constructed.

Using these weights, total scores, obtainable through hand or machine scoring, are found for each scale. The raw scores are converted to standard scores and presented upon a test profile. The patterns of scores so obtained reveal an individual's interests in relation to the interests of groups which have been successful in various occupations. A person receiving a high score, i.e., a rating of A, B+, or B, on a scale for a given occupation, is much more like men in that occupation on the basis of his interests than is a man selected at random from the general population. From the test scores he can conclude that he bears a marked similarity to men who have been successful and who have persisted in certain occupations.

Scores obtained on the Strong Vocational Interest Blank have both relevance and stability. Follow-up studies conducted over several years have shown that:

Men continuing in an occupation for nine or ten years on the average obtain higher interest scores in that occupation than in any other.

Men continuing in a given occupation obtain a higher interest score in that occupation

than men entering another occupation obtain on that scale.

Men continuing in an occupation obtain higher scores on the associated occupational scale than do men who change from that occupation to another.

The test has not been shown particularly useful in predicting degrees of success when only successful men are studied. It has been shown to predict relative success in some fields, including life insurance selling. It also has a slight predictive value in regards to school grades. In general, the test appears of much less value in differentiating the relatively more successful from the less successful than in differentiating the successful from the failures, although conclusive evidence is not yet available regarding this.

Interests as measured by the Strong test are stable enough to be used in guidance. The reliabilities of the men's scales vary from .73 to .94. Over a period of 5 years, the correlations between test and retest range from .59 to .84 and over a period of ten years the correlations range from .51 to .83. Although small, systematic changes occur in interests with increasing age, these changes are not great enough to vitiate the usefulness of the test.

Whereas the Strong test is the outstanding example of an empirically developed vocational interest test, the Kuder Preference Record, developed by J. Frederic Kuder, is the outstanding example of a vocational interest test which has been constructed upon a rational, rather than an empirical basis, and later empirically standardized and validated.

The psychophysical method of paired comparisons was used in the development of this test. The first form of the test consisted of forty groups of five activities. The subject ranked the items in each group in order of preference. Thus, in ranking the five activities, the subject had to compare each activity with every other activity in the group, consequently indicating ten preferences. The forty groups in the blank produced 400 preferences. The blanks were then scored for preferences for a number of types of activities. Some responses were interpreted as indicating a mechanical preference and were scored accordingly. Others were interpreted as indicating a literary preference and were so scored. In this way tentative scoring procedures

were developed for several areas—business, science, music, athletics, social prestige and annoyances.

The items were then analyzed and revised and reselected and the first finished form of the test was published containing scales which provided scores in seven different areas and with reliabilities ranging from .61 to .93. The most recent form of the test has added two scales. After the scales were developed, the test was administered to adults in different vocations and to students in different curricula. In this way, the validity of the test was determined. Commercial airplane pilots were found to receive their highest scores on the mechanical scale; writers received their highest scores on the persuasive and literary scales and nurses received their highest scores on the social service scale.

The essential difference between the above two types of interest tests is that in the case of the Strong test, the scores assigned to each response were originally assigned upon the basis of the responses made by occupational groups. In the case of the Kuder test, the scores were originally assigned upon the basis of the decisions of judges and later the results of these judgments, or total scores, were compared to the scores of occupational groups. In each case, a test is produced which is capable of differentiating occupations and measuring vocational interests with satisfactory reliability.

The interests measured with different techniques are not the same thing, as is shown by the far from perfect correlations found between various indices of interest. The intercorrelations between seven different interest tests of varying validity and reliability range from —.03 to +.74. Correlations between the Cleeton Interest test and the Strong test range from —.16 to +.68. The correlations between Strong test scores and scores on a preliminary interest scale based on differential remembering were of the same order. Interests as expressed by occupational choices also bear a limited relation to other expressions of interest. A contingency coefficient of .50 was found by Darley between vocational choices and scores on the Strong test. Strong found that of 156 college students, 46 per cent entered the occupation in which the highest interest score was obtained; 26 per cent entered the occupation of the next highest score; and 18 per cent entered an occupation in

which no interest was shown by the test. Different measuring techniques reveal different kinds of interests; and an interest revealed with one scale may not appear when a similarly labeled scale of another test is used. A greater resemblance, however, is found between generalized personality patterns found on different tests than between specific interest scores. These patterns are of greatest usefulness in individual counseling.

APPLICATIONS OF INTEREST MEASUREMENT

Interest tests are widely used by clinical psychologists. Educational interest tests are used in helping students select appropriate curricula. Vocational interest tests are used for purposes of vocational guidance and rehabilitation, employment and selection, college admissions and counseling and industrial upgrading and placement. During the five years preceding 1944, one of the largest university personnel and counseling agencies in the country administered 10,334 vocational interest tests exclusive of several thousand tests administered for purposes of college admissions and college counseling programs in the same university. Many thousands of vocational interest tests are being given in the rehabilitation programs of the armed services, both to men and women in the Army, Navy and Marine Corps.

In interpreting vocational interest tests, counselors make use of the concept of occupational hierarchies. During the first world war, psychologists found that jobs of men in the Army could be arranged in order of the average intelligence of the men in these occupations. Thus, near the top of the list were various professional occupations—engineering, law, etc., and near the bottom were relatively unskilled jobs—teamster, factory hand, etc. This occupational hierarchy based upon intelligence agrees closely with the occupational hierarchy based upon the Occupational Level scale of the Strong Vocational Interest Blank. Later the workers of the United States Employment Office, following the leads offered by Trabue and Dvorak, found that jobs could be arranged in terms of the more specific abilities possessed by the people in these jobs. Some jobs were closely related to certain other jobs and if a person had adequate ability for one of these jobs, he would probably have adequate ability for the others.

Occupations have been found to arrange

themselves into families also upon the basis of the vocational interests of the people in these occupations. This was first forcefully demonstrated by Thurstone in his factor analysis of the Strong Vocational Interest Blank in 1931. Through multiple factor analysis, he showed that four factors could be identified in the test and that the amount of each factor represented in each of 17 occupational scales varied. On the basis of this variation, the occupations could be divided into occupations involving work with science, with language, with people and with business. Included in the first group of occupations are medicine, architecture, and psychology. Included in the second are law, journalism and advertising. In the third group are teaching, ministry and personnel work and in the last group life insurance salesmen, real estate salesmen, and purchasing agents. As new scales have been constructed for this test, later analysis has disclosed that all occupations cannot be adequately described in terms of Thurstone's four factors and certain jobs still remain relatively unique insofar as the interests possessed by people in those jobs do not closely resemble the interests of other occupational groups so far studied. For example, the correlations between the scale for certified public accountants and the other occupational scales of the Strong Test indicate this occupation does not fit well into any of the job families described.

The assumption of occupational families has been made in the construction of the Kuder Preference Record and the occupational titles themselves are not used at all in the presentation of test results. The scores are in terms of mechanical, computational, scientific, persuasive, artistic, literary, musical, social service and clerical interests. From these scores the inference is made regarding interests in specific occupations.

JUNG, CARL G.—Carl G. Jung, the world-renowned Swiss psychotherapist, teacher and writer on psychological topics, was among the pioneers in so-called Depth Psychology, ranking with such men as Janet, Freud, Adler and Prince. An early participant in the psychoanalytic movement, Jung introduced some of its leading concepts and was the first president of the International Psychoanalytic Society, from which he resigned because the group was dominated to a constantly increasing degree by doctrinaire, Freudian pansexualists in later years. Among other psychological concepts, introduced by Jung, and later used by Adlerian Individual Psychologists and by Freudians as well as by Jung's followers, the Analytical Psychologists, is the concept of the psychological complex. Jung defines a complex as a group of associated ideas, or response tendencies, sharing a common emotional tone and having common psychogenic roots. This concept is among the pivotal ones in the Jungian system and, indeed, sometimes Jung calls his whole viewpoint "Complex Psychology," reserving the term Analytical Psychology for his therapeutic technique.

Jung devised the discrete-stimulus word-association method as a technique for detecting and exploring complexes in the individual psyche. This method consists of presenting to the subject, or patient, a number of words after instructing him to respond to each by immediately uttering any word that first comes to mind after the stimulus is presented. Sometimes a hundred verbal stimulus-response sequences may be recorded and analyzed, and sometimes several hundred are required. Jung has developed several lists of stimulus-words to be used for seeking complexes. These word lists, however, are of two main types. One type consists almost entirely of words which have an emotionally neutral significance for most persons. Another type includes very many words which often provoke emotional responses. Jung considers the content of an individual's responses to the stimulus

words to be significant but other factors, such as the timing, the accompanying gestures, involuntary movements and so forth, are considered revealing, also. Slow responses to particular words, responses having an unconventional content, deliberately changed responses, responses accompanied by notable expressive movements and other types are checked as possible indicators of a psychological complex. Later, the relations between the various indicative responses are investigated and a tentative construct, representing the complex, is formulated. This construct is considered to be a hypothetical representation of the complex which must be checked by further observations of the patient's responses in clinical situations. This general method has been widely adopted by clinical psychologists and mental hygienists who are interested in investigating individual eccentricities of many kinds but who are not associated with any school of depth psychology. Many American academic psychologists have endorsed the discrete-stimulus method as a device to assist in personality analysis, and more particularly in the analysis of the neurotic.

Jung also accepts the concept of psychological symbolism. He believes that some dream contents may be symbolic, and he has done much pioneer work in the symbolism of folk myths, of religious rituals and of art. He also stresses the analysis of individual fantasy-productions and expressive drawings or paintings. Jung's views regarding symbolism stand in striking contrast to the Freudian view. For example, Jung strongly repudiates the notion that any particular image may have an identical symbolical meaning in the productions of different individuals. He regards emotive meanings as highly personalized and emphasizes the principle that any symbol must be interpreted with reference to its total symbolic context and, indeed, with reference to the yet broader matrix of individually meaningful behavior in general. This principle Jung calls the principle of "Amplification." In seeking to amplify the immedi-

ate reference of a symbol, Jung always considers not only the momentary context, but also the temporal context. He relates the particular symbol with symbolic productions by the same individual in the past, and he also asks whether the momentary symbolic expression has a "prespective" significance for the subject's future adjustments.

Prespective analysis has always characterized Jung's work and differentiated it from other approaches to the so-called unconscious mind. Indeed, he first became interested in depth psychology in 1898 when he studied a case in which one segment of a split personality seemed to anticipate the future, re-integrated self. Jung considers many neurotic episodes to be essentially crises of development. He occasionally has asserted that even regressive episodes in which immature habit-patterns are re-activated must be interpreted as preliminary stages in an attempted advance toward adjustment which shall be more adequate than any that has characterized the particular personality, prior to the regressive episode. Many of his interpretations are, therefore, finalistic and teleological rather than reductive and mechanistic in character. The principle of the "autonomy of the psyche" is stressed throughout the whole system and Jung repudiates all merely biogistic approaches to psychology. He believes that the psychic cannot be reduced to biological categories and that the biological cannot be reduced to physico-chemical terms. Higher levels of functioning obey the laws of lower levels but they also exemplify higher laws which are irreducible.

Jung does not believe that the same psychotherapeutic methodology is applicable to all patients. He distinguishes between the introverted type and the extroverted type. The introvert may adjust happily to his world only on the basis of a personal philosophy, or a religious orientation, or some other functioning world view. The introvert demands a high degree of coherence in his interpretation of his various problems and of their relations to his environments, including even the total cosmic environment. The extrovert, on the other hand, may attain adjustment on a more pragmatic or positivistic basis. If he is given the opportunity to function in socially acceptable ways, and can win commendation while at the same time releasing his biological tensions, the extrovert may

be happy without considering the cosmic relatedness of his own behavior. For Jung the whole distinction between the types is methodological for psychotherapy and is also a relative distinction since he has found that only a very few patients are pure introverts or pure extroverts. Jung has never asserted that the introvert is necessarily a socially maladjusted individual. He has never associated neuroticism with introversion as defined according to his system. On the other hand, he has never defined the extrovert as being emotionally trivial or intellectually inferior. These misinterpretations of Jung's views have gained some notoriety, however, especially in the United States of America where simple, behavioristic philosophies of psychology have had the greatest vogue in the recent past.

Clinical observations have led Jung to the conclusion that in any personality either thought, feeling, sensation or intuition is more highly developed than are the other three functions. Thus he speaks of an introverted feeling type, an introverted thinking type, an extroverted intuitive type, an extroverted feeling type, and so on, through all the possible combinations. Functions which are undeveloped in the conscious personality, however, may undergo unconscious development. Thus a person who overtly exemplifies the extroverted sensation type might possess certain latent introverted intuitive capacities. Indeed, Jung affirms that a dialectical relationship usually obtains between the conscious orientation and the unconscious set.

The most widely rejected Jungian theory is the theory of the "Collective Unconscious." Jung teaches that every symbolic production must have a certain significance arising from a personal unconscious and yet simultaneously must have a deeper, collective meaning. In the analysis of the individual Analytic Psychologists explore first of all those associations which illuminate the personal levels of the psyche, and then, as a second but decisive stage in the analysis, they try to detect connections between expressed contents and the internal collective heritage. These conceptions, unusual in the context of twentieth century psychology, first occurred to Jung when he noted the similarity between the fantasy-productions of certain neurotics and the content of folk-myths. Personal rituals and ancestral folk-rituals were also found

to be similar in many cases. Jung also believes that more basic than any particular ancestral heritage is the "libido," a really universal, purposive life force. Individual lives are differentiations within that universal stream; racial groups, too, are considered as differentiations, but the latter are more inclusive. As the individual psyche is progressively analyzed, less and less personal areas are reached, and each successive area contains contents which are more universal than are those of the more accessible strata. Thus the "libido" may be individualized in substance, but in kind it is universal. Sometimes Jung speculates, with the Hindu philosophers and with the German Idealists, that individuation itself may be a superficial and perhaps partly illusory process.

In the analysis of the individual Jung first of all investigates the nature of the overt, highly socialized aspect. This aspect of the total personality usually represents a compromise between the conventional sanctions and the ego-interests. This most superficial, readily accessible aspect he calls the "Persona." As a second step Jung explores the "Ego," which is only partly socialized and which may be represented schematically as overlapping the boundaries of consciousness on the one side and the unconscious mind on the other side. Unconscious ego-contents are purely personal, representing repressed episodes in the personal life history. Further analysis always leads toward the revelation of the collective unconscious, and the "Shadow" self stands on this deeper boundary. The "Shadow" system rejects many ego interests and ego ideals. Its tendency is anti-social, sometimes even criminal, and yet is not merely egoistic. It is not only more regressive than the ego system but may have characteristics which can only be suggested by employing such terms as "diabolical." Demonology, both religious and merely esthetic, is considered by Jung to be in some degree a projection of the "Shadow." The devil image is a true "Archetype" of the collective unconscious.

The "Animus" and the "Anima" are also archetypes. The "Animus" is an unconscious mate-ideal in the female psyche and the "Anima" is an unconscious mate-ideal in the male psyche. However the significance of these images is much richer than just that. Closely related to the "Animus" is the ideal of the "sage," or "famous wise one," and closely re-

lated to the "Anima" is the ideal of the "Great Mother." Both the male psyche and the female psyche are said to contain both major archetypes. But the relation between specific archetypes and the personal unconscious differs in the two cases. Thus Jung believes that the sage ideal may become an ego ideal for the maladjusted man who is striving toward wholeness of personality, but that it would not become an ego ideal for a sexually normal woman. The precise nature of these and other archetypes varies in different racial groups, and Jung does not think of the archetypes as being inherited as concrete forms. Rather, certain potentialities for archetype formation are inherited. Thus even the collective unconscious may be personalized in some measure, as the experiences through which the potentialities are realized may differ radically in different life histories. Nevertheless Jung considers the possibilities for personalization to be definitely limited by the character of any specific collective inheritance.

Jung stresses the role of religion in personality development and adjustment. He states that a high percentage of maladjusted adults would not have become seriously neurotic could they have developed an intellectually respectable affirmative world view. Also, the development of an intellectually and emotionally satisfying personal religion is considered an essential aspect of the therapeutic process in many cases. The finally achieved "self," the end product of that process, is felt by some patients as *being an introjection of supramundane values*. As a psychologist Jung accepts no particular creed or doctrine but he is strongly convinced that, by and large, humanity requires religion, and that personal maturity in the majority of cases includes satisfactory adjustment to a cosmic setting which is conceived in spiritual terms in the last analysis. That only a small minority, those being, of course, extreme extroverts, may achieve and permanently maintain fullest integration and utmost joy in living without some at least quasi-religious orientation toward their most universal environment is Jung's firm conviction, based on a lifetime largely devoted to clinical work and field observations of human behavior. This viewpoint is still a minority one in modern psychological circles, but there is now a definite trend in that direction as the more naïve mechanistic and reductive views are re-

pudiated by a psychology which is rapidly approaching methodological and philosophical maturity.

Jung's philosophical position stands somewhere between pure vitalism, on the one hand, and holism or organismalism, on the other. Self-knowledge he regards as the completion of a "phenomenology of the psyche." This viewpoint may be criticized, since the deeper psychic strata could be known only through inference and not through direct phenomenological exploration. The term Integral Phenomenology may be applied to the systematic exploration and description of personal worlds. Likewise, the continuum of expressive behavior may be said progressively to reveal a personal world if the continuum be adequately interpreted within a non-physicalistic, phenomenological universe of discourse. But the psyche always transcends direct experience and appears in no personal world. It is not introspectively known, nor does the exploration of another's personal world reveal it. The psyche is "known" only through constructive inference from the data of a personal world, and therefore is a conceivable metaphysical entity which may, or may not,

actually exist. The question is a philosophical one. Therefore, while the term Integral Phenomenology has an evident methodological validity, Jung's usage of the term "Phenomenology of the Psyche" may be questioned on methodological and logical grounds. Theories about a finite psyche, or about an infinite psyche, (and Jung seems to accept both types of theory) are metapsychological theories and, in a more general sense, belong to that part of systematic philosophy which traditionally has been called "metaphysics."

L

LANGUAGE AND PSYCHOLOGY.—

"There is at bottom very little difference between men," said the old carpenter whom William James was fond of quoting, "but what little there is, is very important."

To observe and to understand—and thus to formulate laws which may serve as bases of prediction and which must necessarily be revised again and again as the horizons of observation and understanding expand—the "very little difference between men" has been the business of psychology since first it interested itself in the problem of "the personal equation." To this problem it owes its identity as an autonomous science, and its prestiges have been heightened or lessened in accord with the measure to which it has illuminated and provided clarifying hypotheses regarding one or another aspect of the equation.

We propose here to report on some of the ways in which psychology has employed "language" in the delineation of "personality." We have set aside for a different context (4) the "language" of the mathematician and the natural scientist and thus, also, the linguistic customs and usages of psychologists in the formulation of problems and the evaluation of results (3).

In mathematics and the natural sciences—whose business is primarily the "external realities"—conceptual, pure, logical thinking has to maintain itself against the phantasies, dreams, myths and ideologies, and imagery which are embedded in the linguistic usages and customs of non-scientific thinking. The circle, the triangle, the sphere, number, force, matter, the atom and so on attain full and exact scientific meaning precisely because logical thinking rigidly excises all "inner realities." The linguistic cloak of mathematics and the natural sciences is, as Vossler (61) notes, pronominal not nominal; it points and refers to things; its mood is imperative; its tenor is copulative, equational, operative, executive. The linguistic cloak is conventionalized so as to avoid confusion. Itself,

it is otherwise irrelevant. Jupiter is not a planet as it is to us who are not astronomers; the astronomer's thinking about this particular planet is not befuddled by visions of the antics, the wrath and the amatory, predacious excursions of this phantom of mythology. The planet Jupiter could just as easily have been given a number or a letter. The accent, in these sciences and mathematics, is on the conative. They have freed themselves from an equation of "inner" with "external" realities; they have defined their meanings or goals with reference to the latter and have envisioned some of the obstacles or frustrations; and are now prepared to carry out, to operate, to execute in order to attain the goals.

Not every scientist nor every mathematician frees himself completely from personal phantasy in the execution of his scientific premises. Since complete freedom is a *sine qua non* of the natural sciences and mathematics, it might easily constitute an index of greatness in these fields. Any revolutionary discovery will reactivate personal phantasy and the sometimes easy, sometimes difficult process of excising must be experienced before conceptual, pure, logical thinking is again attained. One has only to review the history of science's reactions to the discoveries of Galileo, Copernicus, and Einstein to obtain innumerable illustrations. Crenonious, for example, would not look through Galileo's telescope lest what he might see might be contrary to what he felt he should not see.

The personal phantasy that realizes itself in the subject-matter of mathematics and the natural sciences is irrelevant in this context. It is important to note, however, that it receives expression in extra-scientific outlets—politics, literature, poetry, economics, psychology, music, drama. If the criteria of conceptual, pure, logical thinking are imposed likewise upon enjoyment of or participation in these media, which involve people not merely atoms and so on, it is easy to surmise—after careful investigation—that these expressions are spurious and simply the

broken threads off one personal phantasy. In such instances, the inner language (6r) has not been negated and the linguistic cloak of logical thinking is merely the device whereby it is hoped to eradicate the paradoxes and contradictions of inner experiences and thus to create "order" out of chaos. I have recently been informed by a scientist whose interests are spread over philosophy, physics, and semantics that the earth will cease to move in something like five billion years and that psychology must adjust its thinking accordingly. This observation seems to me to be relevant only for the problems and the subject of the sciences which noted it. Extension of this observation and others not so far distanced to problems of personality is predicated on an illusion—the tremendous strides made in the physical sciences and mathematics lead some to believe that they have created facts, that there was chaos, too, and contradictions and paradoxes in the external realities before a men-made order dispelled them. Seemingly, the elements in nature were neurotic and perverse until men beat upon them with their "conceptual, pure, logical thinking," just as the Chinese successfully warded off the coming of a comet for two thousand years by beating nightly upon gongs.

Some people are wont to express surprise over the "naïvetés" of the pronouncements on extra-scientific matters by eminent scientists or over the whimsies of a Lewis Carroll. They expect authoritative statements, free from doubts and uncertainties and from personal bias, in which a always equals a —in which there is no dialectic. They are disappointed because the "naïvetés" and the "whimsies" do not provide freedom from their own doubts and uncertainties and do not express their own personal biases and dialectics. They forget—or do not know—that in the exact disciplines that Venus, for example, is not noted to have certain operations simply because of prejudice towards the nominally male planets. They forget—or do not wish to know—because they do not wish to realize that men are often pro-this because they are anti-that or anti-this because they are pro-that. The linguistics of the "pure" sciences is adapted to the needs of the situations in which they are pursued. The linguistics of men are likewise adapted to their needs; perhaps in five billion years the two will meet.

"The need for authority," says John Dewey

(16), "is a constant need of man. For it is the need for principles that are both stable enough and flexible enough to give direction to the processes of living in its vicissitudes and uncertainties." Six little words seem to take up all man's day (6r): "I should, I must, I can, I shall, I will, I may." But he knows not "What I should, I must, I can, I shall, I will, I may." Too many psychologists would refer man for instruction to the linguistic systems of the exact, pure sciences. Korzybski's theories—if not his practices—find the seat of authority in the new orientation in physics (53). The how's and why's of man's behavior and the devious ways in which they are predicated on the what's are dismissed as irrelevant. Yet what, how, and why are questions which are posited by even mathematics and the natural sciences. In solving the riddle of "the personal equation," too many seek to make the answers mirror the operations noted by the science (or sciences) which first presented psychology with a problem it could make uniquely its own.

Obviously, it behooves psychology to eradicate or at least to be less ignorant of its own personal equation in the study of "the very little difference between men." How to do this is a problem in the language of psychology. The writings of Carnap, Bridgman, Bloomfield, Morris, and Stevens are significant in this context, but are irrelevant in the context of "speech and personality," (53) where one should be able to presume that the investigators are already acquainted with the problems presented to psychology by logic and epistemology. The studies of the many implications of the "halo" effect and Ferenczi's (17) *Belief, Disbelief, and Conviction*, among many others, would be more helpful.

Psychology seems to equate forms with internal and external realities. It fails to note that the linguistic economy of the sciences it idealizes was factored out by the experiences of men who were scientifically curious about phenomena whose time-space-pace and other relations differ from those of men. Psychology cannot eradicate its own biases merely by delimiting the scope and depth of its observations or by parroting an argot. Baggally's (9) application of quantum mechanics to "hedonic conflict and the pleasure principle" does not advance the study of personality even though—with reference to certain equations—he says: "It is my

opinion that we have here the explanation of the primary sadistic impulses directed against the mother . . ." The language of topology even detracts from the intelligibility of its otherwise cogent scientific observations. No amount of mathematical virtuosity in delimiting and parroting will alter the fact that scientists operating in the pure sciences have no need for metaphors, elisions, ellipses, synecdoches, for adjectives and adverbs, for nouns and personal pronouns, for monologue and dialogue, for moods and drama,—and that men do.

The exact sciences, as noted, attained conceptual, pure, logical thinking attained chastity by eliminating personal phantasy, dream, imagery, myth and ideology. They could then cognize in unprejudiced fashion and thus evolved many theorems which were to be tested. The accent, as already noted, was on the conative.

We now come to an aspect of the investigation of speech and personality in which the accent is on the cognitive. The problem of personal phantasy is eliminated either by considering any deviation from the communal phantasy as pathologic or by categorically insisting upon the adoption of one or another communal phantasy. The approach is normative. This is ingeniously—by reference to the etymologies of words—and ingeniously disguised; so much so that we can only quote at some length from Galt's article on *Our Mother Tongue* (24), in which he attempts to show that the "body of linguistic data" massed by Burrow's phylobiological researches "correlates nicely with the phylobiological orientation."—

"An important aspect of Burrow's thesis is his altered orientation in respect to the 'good-bad' or 'right-wrong' antithesis that everywhere pervades the sphere of human behaviour."

"Their external manifestations may be quite diverse but the internal behavioural mechanism is the same. Whether bad or good, the individual is reacting momentarily in the way he reflexly feels is more advantageous to his 'social image' of himself. The moral course which an individual will follow is thus entirely variable and arbitrary."

"Accordingly, the primary motivation of man is not expressed in the desires, wishes or phantasies of the individualized self but is basically oriented in relation to the needs and integrity of his biological group. In man's socio-sym-

bolic development, however, there has occurred a biological trauma in which the individual has been split off in feeling and motivation from his phyloorganismic matrix. The part (individual) has inadvertently received more stress than the whole (species), and this unwarranted emphasis has resulted in a false splitting and individuation within the behavior-processes of man as a biological unit or phylum. This divisive substrate issues in a systematized distortion and symptomatology analogous socially to the distortion and symptomatology that is induced in the neurotic or psychopathic patient by a cleavage within his total personality as an individual."

"*Das Kind*, German for 'child,' signified in its original, broader meaning one's *kind*. The child was not looked upon as a new personality belonging to a specific individual; it represented an intrinsic member of a generic group."

"The group solidarity of original man is further evidenced linguistically in the findings of the comparative philologists who point out that the languages of many primitive peoples have no word for the first personal pronoun of the first person singular. To quote from Dr. Margaret Schlauch's very interesting book, *The Gift of Tongues*: 'There is reason to believe, indeed, that the first person pronoun (singular) was a comparatively late development in some languages. This is vivid grammatical testimony to the relative unimportance of the individual as opposed to the tribe! It seems to imply that in such tribes men could conceive of themselves only as parts of a larger social whole. In such cases it was not possible to say 'I do this,' but something like 'People do so-and-so by means of me, John.'"

"Knowledge is ulterior, consciousness strategic. Cognition is close kin to pride. It is one with *self* as an end. In other words, it is synonymous with acquisition, aim, calculation. Man has in truth made an *idol* of the *idea*, the two being in fact closely related etymologically."

"The distrust of the folk-mind for the word and the symbol, for mentation and knowledge, is clearly shown in certain Biblical references as well as in certain etymological relationships. Take the word *knowledge* itself. According to Biblical tradition the Fall of Man was brought about through his having 'eaten of the tree of the *knowledge* of good and evil.'"

"The result is that language as now used by

man is not merely an evasion of man's commonness but actually favors the expression of neurosis and war."

Phantasy, dream and imagery, myth and ideology (vide the etymological citations) are rampant in this purportedly systematic approach to the study of personality. "The purposes of language, of course, is communication." "Its development has been a potent factor in man's survival." It is a "somatic function," "produced through the action of definite body-parts." Hence the perturbation over the intrusion of the self, cognition and experiential content and values—these Burrows as a psychiatrist can not dismiss as summarily as Watson did! Hence the nostalgia for the Past, the placing of the norm in phylogeny and not in ontogeny!

In this context, where the accent is on the cognitive, it is easy to trace the intrusion of phantasies evolving from Descartes' "I know; therefore I am" and Kant's "I ought; therefore I can." It is not surprising then that the sole function of language is communication and that the rich experiences of men embedded in language are reduced to a particular scale of meanings (lexicon) and to a particular scale of linguistic habits, traits, and style (grammar),—all of which proves neither that "I am" nor that "I can." Communication is conceived as "produced and forged by the social environment (3)" which provides the individual with a made-to-order logic in the form of a grammar and lexicon. Ignoring the experiential content of the individual, especially in the case of subjects whose native-tongue is English, creates a dilemma in interpretation and evaluation of results—the English language, whose lexicon is the largest of all lexicons and whose grammar is notoriously vague, has always sacrificed "logic" and vocabulary where the logic of facts or of the exterior world disagreed with the logic of grammar (5).

The origin of this approach in comparative philology may be traced to what Jespersen (35) calls "eye-philology." This philology ruled almost exclusively until the early nineteenth century. It evolved around the teaching and usages of Latin. Latin was taught chiefly as a written language, not as a means of opening up a rich store of literature to the masses, or even to the elite, but as a practical and highly important means of communication between educated people. One had to read and write—and speak

it as if one were reading or writing—if one wanted to maintain, however humble, a position "in the republic of learning or in the hierarchy of the church." Its grammar was regarded not as a set of observed facts but as rules which must be observed and obeyed. Its vocabulary was treated in like manner. The usages of grammar and lexicon were intractable and invariable. Their logic was given as corresponding to some order in the universe. The teaching of Latin was *normative*—questions regarding behavior and thinking were settled by whether or not they conformed with Latin usages. Not only thought but all the nuances of experience were considered as coextensive and commensurable with language.

This normative, prescriptive, restrictive view of language was extended to French. As Vossler (61) notes: "In the centuries of Descartes and Voltaire the whole language was intellectually refined and trained to that type of hearing for which *entendre*,"—"to think properly, to know"—and no longer *ouïr*—"to hear"—was the correct term. Vaugelas, the great master of language of that time, says: "that it is much better *satisfaire l'entendement que l'oreille*, wherever the demands of the ear do not coincide with those of the rational intelligence."

Piaget's monumental works are embedded in such traditions. They are mainly concerned with the *thinking* of children over four years of age and are based on observations, conversations, and experiments at the *Maison des Petits*. Piaget argues, among other things, that the child up to seven or eight years of age is non-social and non-egocentric and thus he commits errors of syncretism (causal relation of two unrelated phenomena) and transduction (inference from one instance) and that it is essentially different from that of the civilized adult in that it is animistic and in other ways similar to primitive man's.

Rose Chadwick notes that Piaget generalized from too few cases and suspects a significant number of the children were below average in intelligence. Susan Isaacs (48), experimenting with children from under three up, gives a wealth of illustrations to show how acutely and perseveringly children puzzle out solutions to *their own problems* and demonstrates that the child's thinking is not fundamentally different from that of adults—it only seems so because there are so many more fields in which his

knowledge is inadequate, and even an adult's thinking may be syncretive and transductive in situations where he does not have the requisite knowledge. Burt, writing some years ago, declared that he found no evidence of any specific mental processes that could not be performed by a child of seven—that there is no age limit in relation to the processes of thinking, beyond that imposed by lack of experience. Piaget's theory, according to Hazlitt, implies that children under seven are scarcely capable of thinking. Hazlitt notes that the adult makes the same mistakes as the child when he is confronted with wholly unfamiliar material; he even makes mistakes with familiar material if he has not been obliged to concern himself with it previously. For example, Piaget tells how children, in accounting for the displacement of water by objects of different size and density, sometimes give weight and sometimes size as the cause without bringing the two into relation or seeing any difficulty in giving different causes for the same phenomenon. Hazlitt obtained the same results with non-scientific adults, who were no more disturbed by the contradictions in their answers than were Piaget's children. Hazlitt questions further two assumptions, which Piaget himself admits in different contexts are not justified, upon which are based "obviously false conclusions,"—thinking can be identified with ability for verbal expression and that the content of thought is indifferent to the process; for instance, if a child cannot think a relation in regard to one subject-matter, he cannot think it in regard to another. And finally, Piaget's assumption that children are naturally non-social in their thinking until the age of seven or eight has been and is still questioned by psychologists, as well as by psychoanalysts and educators. Baldwin and Stecher, for example, note social conduct and a degree of cooperation among children as young as two years of age in circumstances favoring and giving ample opportunity for it. They stress, however, that very few children under five, and even fewer under three, have such opportunities, which can come only to the child who is with others of approximately the same level of development.

Piaget's *satisfaisant l'entendement que l'oreille* biases are acceptable to behaviorists in both the psychology and language camps. His precise equational formulations embrace only sign and

referend—thinking and language are reduced to the mechanical and automatic level of the speech of a parrot. His rationale excludes both referent and referee. His "society" is the bleak *Maison des Petits* and the scholastic traditions embedded in its curriculum; the "code" of this "society" over-evaluates verbal expression as a measure of thinking and exaggerates the logicity of adult thought. His isolating of one sign from so many others determines the subject matter and defines the method of his investigations. Thus, he can easily derive generalizations regarding the emergence serially of thinking in linguistic habits and forms, each one unique and invariable in function and content. These generalizations, though admittedly falsely premised, are utilitarian; they apparently fulfil a need for something as fixed in the universe of men as is found in the universe of nature; moreover, they have the semblance of having evolved from "conceptual, pure, logical" thought. And all these enable the behaviorist to suspend his disbelief of cognition and his aversion to its irrationalities.

The bibliographical reviews of Esper (16a), Adams and Powers (1a), McCarthy (1a), McGarahan (1a), and Sanford (53), all endorse a behavioristic treatment and explanation of the problems of language—regardless of whether the problems relate to the language of psychology, the psychology of language, or language and personality; all endorse further Piaget's evaluations as the strategic point for either inquiry or interpretation or both. The implication of these endorsements, as I have indicated in other contexts (3), is manifold: they over-evaluate scientific method or technique to the exclusion of scientific temper or spirit—facility of verification guides the selection of facts and predetermines their relevance, not a certain humble devotion to the subject matter, be it the behavior of natural universe or of men. Moreover, the reviewers utilize as "proofs" or "disproofs" of their premises the results of investigations otherwise premised. They fail to heed a caution in literary criticism which should be applied in scientific criticism:

"In every work regard the writer's end,
Since none can compass more than they intend."

Thus it is that "the style is the man" becomes the slogan in studying speech and personality,

in Gestalt and topological psychology as often as in behaviorism. The style is no more the man than an electrocardiogram is a man's heart or a recording by Frank Sinatra is Frank Sinatra. The style is the man only if it is presumed that he does not see, think, feel and judge—and act, even though it be in the form of an inaudible retort or a shrug of the shoulder—as he listens to others, that he does not hear, think, feel, judge and act as he reads or writes, and that speaking, reading, and writing are self-contained, not reflections of the form and content of orientation to a situation.

Gardiner (25) recognizes that the style is not the man when he draws an arbitrary, artificial distinction between language and speech:

"New combinations of words, newly coined words, new uses for old words, as well as such terms as intonation, rhythm, emotional and affective factors, personality traits, all operate to make of speech a living, ceaselessly changing thing rather than a collection of stereotyped sounds. If any speaker repeated a sentence of any considerable length in exactly the same way, the duplication would be laid to coincidence. So important is this contrast between the new and the old in spoken communication that it has been proposed to apply the name language to the relative static dictionary and grammar element, and to reserve the term speech for the adaptable, living drama of actual communication."

Pear (48) makes no such artificial demarcation between speech and language. In an article on *Speech as an Expression of Personality*, he notes that in England there is "an interesting taboo upon criticising, even mentioning a person's voice or speech"; the taboo does not apply to his writing, painting, music, sculpture, or sports. Nevertheless, he proceeds to analyze "public speaking." Its flaws, he discovers, are many:

"dropping the voice at the important parts of a sentence, saying nothing in many words, prefacing controversial matters by 'of course,' waiting for the inspiration of the moment (justifiable if and when it comes), reciting series of general statements without illustrating concrete examples, giving concrete examples without indicating the truth which they are meant to illustrate, not observing the effect of one's speech upon the audience, ignoring the type of audience to whom one wishes to appeal,

using the wrong pace—too fast, too slow, or in broadcasting, insufficiently varied, assuming one's audience to be at a fever heat of expectation when (or because) one begins to speak—."

From these and other analyses Pear concludes:

"The psychology of composing can only be hinted at here, yet the predominant mental imagery of a person who, with dictaphone, pen, or typewriter, is preparing the manuscript of a talk, will influence greatly his choice of matter and of manner."

The role of "mental imagery" is strikingly illustrated by the alliteration in Shakespeare's sonnets. This—as a study of literary behavior—has been made a topic of specific investigation by Skinner (58). Alliteration was a poetic device in great favor in Shakespeare's day. Shakespeare himself disliked it and sedulously avoided employing it in his plays. He used it freely in his sonnets—sonnets, it must be noted, are media for the voicing of, if not love, at least the finer and nobler sentiments.

Ford Maddox Ford, in a discussion of *Techniques*, notes that "such advocates of the study of technique as Conrad or Dowson or James or Crane or Flaubert are far more interested in the writer's finding himself than in establishing any one rule that shall cover every tribal lay," and writers, that is novelists, find themselves in their "appeal" to their "fellows" and thus, in writing, must have their eyes on the Reader. Conrad was immensely impressed—and depressed—by the idea of Flaubert's "impeccable unapproachableness"; he was "so divinely jealous" of the greatness of his fellow writers that he often despaired of being more than a mere pedestrian in the world of literature. But these were merely frustrations which he eventually surmounted by consciously developing a new form for the novel—by evolving, among others, "the convention of a Marlow who should narrate, in presentation, the whole story of a novel just as, without much sequence or pursued chronology, a story will come up into the mind of a narrator," and by laying down "as a law that, in introducing a character, we must always, after a few vivid words of personal description, apportion to him a speech that *must* be a characteristic generalization." Ford Maddox Ford, who struggled together with Conrad for over a decade, was immensely impressed, depressed, "divinely

jealous," despairing, in not wholly the same degree or in the same directions as Conrad. He surmounted his frustrations by, among other devices, dispensing with "a narrator" and evolving a technique for the presenting of conversation. "Eternal and universal" appeal, or popularity was Ford Maddox Ford's goal; Conrad's novels may have been only the address of an "I" to its "me" or only an address to his literary idols.

Here we have two novelists who consciously strove for certain effects, who even tell us how they were achieved. Yet we cannot say of either: The style is the man. True it is that we can distinguish a Turgenev, a Henry James, a Flaubert, a Conrad from one another, but not on the basis of structure alone. Content is inextricably bound up with structure. And if we wish to more than merely distinguish one man from another, to understand and know the man himself, we must inquire into his biography and his personal socio-cultural milieu or milieus.

Ford Maddox Ford tells us that Conrad consciously achieved the dramatic in this manner: "This fellow gets that effect by a cadenced paragraph of long, complicated sentences, interspersed with shorter statements, ending with a long, dying fall of words and the final taptap of a three monosyllabled phrase . . . just like that." Try to level this to a "mechanical carrier"! Yet Zipf (70) and Zipf and Whitehorn (71) do this obliquely: they plot logarithmic graphs of data yielded by "type-token ratio" analyses of James Joyce's *Ulysses* and a series of newspaper-writing specimens; against these they plot data yielded by similar analyses of the letters of patients; the deviations purportedly tell us something or other about the language of psychopathology. This scheme does an injustice to the respective skills of the investigators in linguistics and in psychopathology. It is an attempt to find a *norm* for style in "the successful charting of the course of speech between dull over-articulation and incomprehensible under-articulation."

The type-token ratio is the ratio of the number of different words (types) to the total number of words (tokens) in a given passage. Johnson (38) was among the first to employ it in the measure of *consistency* in the study of individual differences in linguistic expression. He recommends it as a more dynamic and

valid measure of vocabulary than simply ascertaining the number of words a person "knows" or can define. He suggests further that it will be found to correlate with intelligence, that it may be used to indicate the "stimulation value" of any situation, and that it may serve as a measure of degree of frustration or of disorientation,—thus the phenomena known as the "one-track mind" or "monomania" become amenable to quantitative treatment.

Zipf (70) himself implies that "types" are not too easy to identify when he writes: "The number of formal words in the vocabulary of any speech-group is by no means so large as the number of potential or actual categories into which experiential data may be or is divided."

A guide has not yet been written for Gertrude Stein. Two authors, however, have collaborated to produce one for James Joyce's *Finnegan's Wake*. It is a little over 300 pages and informs us, among other things, that a specified "neologism" has six different meanings dependent upon the context in which it appears and that the surname of a character in the book is prefaced by different initials dependent upon his role in varying contexts. Yet the type-token ratios of the samples utilized in the study by Zipf and Whitehorn are approximately the same.

The type-token ratio is but a variant of the sign-referend relation. That Zipf subscribes to this approach is implied when he says: "Neither the original meaning nor the etymological meaning of a word is necessarily its primary meaning: the meaning which has the most frequent usage is the primary meaning."

Zipf asserts that "the selection of samples of language may be dictated at least to a considerable extent by the investigator's convenience." Does he not mean: by the investigator's wish? Boder's (10) study of the adjective-verb quotient illustrates—though this was not his intent—that the sample is a significant factor. The *Avq* varies significantly with the subject matter of the text—it was lowest in the ten plays taken from Montrose J. Moses' "Representative American Dramas," highest in scientific writings—we hasten to add that these consisted of 30 specimens from Ph.D. theses, 14 from "Psychologies of 1925," 6 from scientific text books, 30 from Master's theses, and 3 from "The Nature of the World and of Man." The *Avq* varies also from writer to writer—Brisbane's,

for example, coincides with that of fiction, whereas Mencken's corresponds with that of scientific writings. The *Avq* in William James' letters is lower for those to men than for those to women at the age of about 40; the relationship is completely reversed in letters written after 65. Runion (52) also illustrates the importance of the sample—though this too was not his intent. He made a quantitative study of sentence length, sentence structure, sentence "artistry" and figures of speech in 50 speeches of Woodrow Wilson and found that employment of all these variables varied significantly with the occasion. Sanford (53), however, regrets that "these findings . . . in themselves tell little about Wilson's style," though they do "raise the interesting problem of situational determinants in linguistic behavior." Newman (44) and Balken (3)—though their studies are an intrusion in a context which accents the cognitive, prescriptive and normative—stress that the selection of samples of language may not be dictated "at least to a considerable extent by the investigator's convenience."

If the style is the man, the difficulty of identifying its "mechanical carriers" (a) are much greater in scope and depth for men who are not a Conrad, a Shakespeare, or a James Joyce. Fechner satirized quantitative science under a pseudonym; at the same time he carried on exact research in atomic theory, and was engaged in teaching the physics of his day. Which style was he? William James penned delightful letters to men and women; he also wrote *The Varieties of Religious Experience* and carried on teaching and lecturing. Which style was he? Stevens (60) argues that the initial data of description are equivalent with elementary reactions and the sign of a thing is therefore the same as the thing itself:—finger reactions are tonal intensities; scratches on a smoked drum are the feeding behavior of rats; stopping a car at a signal light is the color red; and so on. In language and personality, "the style is the man" is strikingly illustrative of the nonsense which *fondness* for a method can produce about a subject matter.

The cognitive, prescriptive, normative way of viewing speech and personality is fraught with some great dangers which can be avoided only through a comprehensive knowledge of the historic, ontologic—not phylogenic development of men and of the circumstances under which

they acquire, adopt, discard, distort or modify language usages, and by abandoning the Rousseauian linguistic tradition—that the first men set themselves more or less deliberately to frame a language by an agreement among themselves for the purposes of communication and maintaining the *contrat social*. The frustrations arising from lack of "mechanical carriers" will then not be so insurmountable. As Cattell (12) notes:

"The proponents of measurement in this somewhat shadowy world of personality qualities stake their defense on the well known dictum of Thorndike that 'whatever exists, exists in some quantity, and can therefore ultimately be measured.' Unfortunately the optimism engendered in some psychometrists by this excellent statement blinds them to certain basic conditions of measurement, notably to the rule of elementary algebra that added units must be of the same kind. Therefore our first step must be to emphasize that measurement can only follow . . . upon advances in descriptive psychology."

It is difficult to grasp language except by its own metaphors. No attempt, therefore, will be made to describe it other than as a medium or media in which meet speaking, listening, hearing, thinking, conversing with oneself or others, answering, reading, seeing, writing, and so on. Herder was among the first in philology to formulate the beginnings of language in the child in the address of the "I" to the "me"; Freud among the first in psychology to formulate its beginnings in kinaesthesia, visual images and auditory images. Since then the fallacy of assuming a simple, specific derivation for language has been exposed by many investigators in psychology, psychopathology, sociology, and philology. Noteworthy in the context of language and personality are the contributions of Pear (*op. cit.*), Boder (*op. cit.*), Isakower (34), and Wallenberg (63).

Nor can language be defined in terms of the mechanisms for speaking, hearing, writing, and so on. Not only do all men possess the requisite mechanisms, but the mechanisms themselves are not wholly identified with language. They are employed coincidentally or independently for other functions—the mouth, for example, for eating; the vocal chords for coughing; the hands for bringing food or liquids to the mouth; and

so on. This fact is important for understanding the difficulties, resistances, and the many barriers and hindrances towards linguistic expression. It is as yet a relatively unexplored field in both psychology and anthropology. Sapir (54) urged psychologists, philologists, and socioculturalists to investigate it. The observations of psychoanalysts on this score, however, are suggestive almost to the point of bewilderment, whereas those of psychologists have been considered irrelevant for speech and personality and therefore overlooked—the eye-philologically minded psychologist might, at least, review the studies of gestures by Olson (46).

But men may be differentiated in terms of their instrumentation of language, in terms of their linguistic usages. Bergson laments: "Each one of us has his own way of loving and hating, and these loves and hates reflect the entire personality: yet language indicates these states of mind by the same words for everyone." The behaviorists, strangely, echo this lament in their deplorings over both the inadequacies and redundancies of language. But Bergson, it must be noted was speaking and writing of the French language. The attitudes of the French towards stylistic purity may be inferred from an anecdote (19) of Flaubert's violent reaction to young Henry James' joining the chorus of an almost unanimous contempt for the style of Merimee: "To think that an American should dare to have views as to the French of one of the greatest of France's stylists! Only to think it, was enough to make Villon, Ronsard, Racine, Corneille, Chateaubriand—not of course that their styles were anything to write home about—turn in their graves. . . ." Fenced in by such traditions regarding style, the French automatically resort to mimic and articulatory usages—all of which escaped Piaget's attention and interest in his studies of the language and social development of the child.

Gesture and articulatory instrumentation of language is an important feature of language. It would be desirable to include observations of individual differences in gesture and articulatory usages in our inquiry into the ways by which men may be differentiated in terms of their usages of language. Unfortunately, such usages have a long, complicated, genetic, social history and until the beginnings of speech in the individual have been more thoroughly explored we are compelled by scientific caution

to not include this instrumentation in studies of language and personality. It may be referred to as the shell of language; as such it is very important to the language of psychopathology—Klasi (39), for instance, was able to demonstrate that in 21 motor stereotypies not less than 9 were defensive acts against hallucinations of bodily sensations, whereas the others proved to be in part ceremonies, atonements, and so on. A plea for cinematic or dictographic or phonographic recordings may be answered by the comments of Cattrell (*op. cit.*) and the assertion by Zipf (*op. cit.*) that though the phonograph "records with a high degree of accuracy the gross acoustic effects of the stream of speech of an individual," it is "inadequate for dynamic philology as the final representation of speech." The advantages to pedagogy of such recordings is unquestioned; in research there always remains the problem of representative sampling and, most importantly, the personal equation of the investigator. Zeman (69), for example, spoke the German word "hein" into Scripture's speech recorder in three different ways, first as a quiet answer, then as a reassuring question, and lastly as a cross and impatient answer. How could he be sure that his vocalizations corresponded with his intentions, with only a recorder to question and to answer him!

The observation and description of "the very little difference between men" was pioneered in comparative philology by the Grimm brothers (early 19th century). Their primary interest, folk-lore, may have been impelled by a chauvinistic rebellion against Latin as the *sine qua non* of intellectual, social and political life. This in turn may have led them to disregard "the aristocratic narrow-mindedness with which philologists looked down on unwritten tradition, on popular ballads, legends, fairy tales, superstition, nursery rimes . . ." Very early in their endeavors to amass folk-lore, they found that they had to wander from community to community and thus to consider philology. They integrated ear-and-eye philology—"Speak that I may see and know thee." Language for the Grimm brothers was "an unconscious and unnoticed secret implanted in youth, never-resting, changing with time and place." They did not concern themselves with solving the secret, but devoted their attentions to the never-resting, changing with time and place aspects of language. Thus a language came to be viewed as

a repository of the wishes, frustrations, intentions and values of the men who spoke it—a key to their Weltanschauung, as it were. In this wise did the brothers Grimm “create a pattern for the scientific study of culture by comparative investigation of the entire mental life of which written literature is nothing but a small epitome.”

Freud's investigation of the language of the dream and the language used in reporting and associating to the dream led him inevitably into comparative philology. He found linguistic usage, mythology and folk-lore indispensable to understanding the structures and functions of dream-symbolism. Thus, Egyptian, “the oldest language known to us,” expresses two “most inimical thoughts” by “one and the same sound”; it also combines contradictory concepts into compound-words, “not in order to create a third concept, which happens now and then in Chinese, but only in order to express, by means of the combination of the two, the meaning of one of its contradictory members, which alone would have meant the same . . .”—in writing the intended meaning is indicated by explanatory pictures; in speech by gesture. These peculiarities of the Egyptian language, Freud found, appeared in the dream-work—“the word ‘No’ does not seem to exist for a dream. His philological source, in this instance, was a pamphlet by Karl Abel on the antithetical sense of primal words—a contribution to dynamic philology made possible by the pioneering of the Grimm brothers. In this wise, Freud also furthered the development of dynamic philology (3). These and many other observations, scattered throughout his extensive writings, too numerous and unfair to cite out of context, provide clues for identifying language usage variables in the study of personality. Those presented in *The Psychopathology of Everyday Life* must be familiar to everyone. Space does not permit review of the applications of his method of dream analysis to analysis of the language of personality (3).

Abraham, himself a competent philologist, was interested in comparative philology more in the spirit of a virtuoso than in the temper of research. His etymologizings, though entertaining and instructive in context, are not suggestive of clues.

Ferenczi, who seems to have been primarily interested in the perfecting of techniques for the

analysis of resistances, provides many clues. These are especially helpful in the study of speech and personality—contrary to popular belief in psychology, men cannot be made to tell what they can not or will not tell; therefore the investigator can use only what they do tell. If he dares do more and neglects evidences from other sources, however apt his virtuosity, he is allowing personal phantasy to interfere with scientific objectivity. As Zilboorg (72) and French (20) note, perhaps the most significant contribution of psychoanalysis to psychology and the social sciences is a technique for investigating human behavior, itself so highly charged with value judgments, despite the interference of the scientist's personal phantasies. Noteworthy in Ferenczi (17) are the chapters on “Abuses of Free Association,” “The Analysis of Comparisons,” and “Belief, Disbelief and Conviction.” The last named indicates the difficulties of attempting to reconstruct the personality of a scientist or a devotee or rejectee of an “ism” on the basis of merely the language usages of merely some published contributions: these were probably revised again and again before attaining final form and may or may not have pleased the author himself; frequency of footnotes and the fact of footnotes, quotations, bibliography, for example, do not have an invariable context and hence not an invariable significance. Pear's (*op. cit.*) contributions may be profitably re-examined in this context. When one reads or re-reads these articles, one is led to re-examine Sanford's hypotheses for the measurement of “egocentricism” and “dogmatism,” and then to dismiss them as sophistries extrapolated, admittedly, from Piaget by way of data from Markey and Le Brant.

French (20a), in *An Analysis of the Goal Concept Based Upon Study of Reactions to Frustration*, describes “the organization of behavior for wish-fulfilment.” This involves two steps. “The first is a *cognitive* one. One must understand one's situation so as to *know how to reach the goal*. The second step is *executive*. It is necessary to subordinate one's motor energies to just the kind of activity needed. . . . The two fundamental techniques for successfully dealing with an obstacle are (1) attacking and overcoming it or (2) yielding and modifying one's demands to correspond with what is really attainable.” Since language has an important space-time-pace economizing function

(4) in the organization of behavior for goal-attainment, French's formulations provide an orientation in the study of speech and personality—for deriving generalizations which may serve as the basis of formulating problems and organizing data.

Significant also are the contributions of Cattell (12): "An attempt . . . to distinguish and classify the various forms of trait unity in which trait elements are found to be integrated," leads Cattell to say:

"Apparently there exist only three kinds of integration, which have been called *dynamic*, *environmental mould*, and *constitutional unities*. Logical, evaluative, stylistic, co-nascent, etymological, stimulus-response, and other unities, frequently utilized, by implication, in common speech (as indicated by a survey of trait names), have a self-consistency which is either one of the above basic forms, disguised, or which is spurious, nonfunctional, and resident only in the mind of the observer. Of the true functional unities it must be said, however, that since they are relations between a genetically mutable organism and an historically changing environment their permanence is only relative."

The "personality variables comprising the complete personality sphere" were condensed from Allport and Odbert's list of 17,953 terms applying to human behavior and from the psychological literature. Cattell argues the pros and cons of these verbal symbols as representative of the complete *surface* of personality and concludes that the hypothesis that language is "a complete, reticulated mirror to human nature" may be retained despite the "silences on the part of language," since "social experience has . . . performed its own factor analysis by linguistic methods."

These postulates may be extended to the linguistic usages of the individual in his organization of his behavior for wish-fulfillment and to psychoanalytic experience. We can hypothesize that the language usages of an individual are a complete, reticulated mirror to his personality and that psychoanalytic experience has performed its own factor analysis of the whats, whys and wherefores of human nature by linguistic methods. To this Cattell himself seemingly would have no opposition—elsewhere (12a) he maintains that psychoanalysis has attained a technical level in observation and description

yet to be attained by current psychological methods, and intimates that psychoanalysis attains this level precisely because, recognizing the semantics of intrapersonal obstructions to scientific thinking, it has been able to carefully describe and properly systematize a wealth of phenomena hitherto unobserved and therefore overlooked. Thus it utilizes even the silences of language. Ferenczi (*op. cit.*) comments on prolonged silences and sudden silences as manifestations of "association resistance" and on the reactions of the patient to the psychoanalyst's silence; Balken (3a) adapted the technique of the Thematic Apperception Test to delineate the meanings of the "silence" of schizophrenics; and Wallenberg (63) proceeds from the experiments of Fischer—these show the importance of identification with moving objects in our relationship to the outside world by means of visual perception—to delineate the relation of auditory perception to the perception of space and motion and the psychopathologies evolving from defective hearing.

Inspection of Cattell's 171 personality variables shows that only ten refer to abilities. The remaining 161 adjectival or adverbial-adjectival. Zilboorg (72), Scheikel (55), Carr, and Balken indicate, or rather suggest, that adjectival forms express affective judgments about persons and things—whether they affect one pleasantly or unpleasantly. (This may explain William James'—at about the age of forty—employing significantly more adjectives in his letters to women than in those to men.) Psychoanalytic experience reveals that affective judgments are often evaluatively tinged; Cattell tried to eliminate such trait names—he could not, of course, eliminate all the contexts in which the selected trait names might be used. Psychoanalytic experience shows further affective judgments may be condensed in one linguistic form. Though Cattell seems to have successfully eliminated such condensations, the adverbial-adjectival trait names suggest interesting implications for further research. Connotative judgments, as Carr shows, indicate one's attitude to a person or thing, whereas affective judgments indicate how the person or thing affects oneself—one likes or dislikes, whereas the person or thing is pleasant or unpleasant. Connotative and affective judgments are not necessarily positively correlated—one may like what is unpleasant to oneself and dislike that which affects one pleasantly.

The reasons for this seeming paradox are to be found in the genetic, psychological history of the individual. Regardless of contradictions, connotative judgments linguistically express one's intentions; this is the underlying thesis of "likes and dislikes" vocational questionnaires—Ream (50), for example, differentiated two groups of salesmen, the one successful, the other unsuccessful, in terms of "likes, dislikes, indifferences." In other words, connotative judgments indicate what one is apt to do in regard to something (*vide* French). It is not suggested that connotative judgments will be expressed invariably by the same linguistic usages, but merely that linguistic forms be analyzed in context and as to probable content and that Cattell's preliminary analyses and tentative findings are thus significant for speech and personality. It must be stressed anew that affective, connotative and evaluative judgments may be expressed in devious ways—Roback's (51) dictionary of international slurs or "ethnophaulisms" illustrates some of the ways—words (probably adjectival and adverbial nouns), phrases and proverbs.

Since psychoanalysis can dispense with neither contexts or content, nor condensations or judgments, its linguistic methods thus have the advantage, over those of recorded social experience, of seeing and hearing linguistic usages in action, as it were. Thus it has been able to evolve psychological laws, applicable over the whole range of mental life, including rational and irrational behavior, and hence invaluable to investigation into speech and personality.

It must be remembered that such investigation would not be possible without the earlier—and contemporary—work in the fields of perception, reaction time, intelligence, vocation and pedagogy. There is a tendency among psychologists to ignore contributions from these fields as irrelevant and even obstructive to the study of personality. Boring stresses that a sophistication which is not historical is no sophistication at all. The compulsion to neglect its own history accounts for the present predicament in inquiry into language and personality whose problems are confused with the language of psychology and the psychology of language.

EVA RUTH BALKEN,

LANGUAGE, THE PSYCHOLOGY OF.

—The present article will restrict itself to those phenomena of speech of which there are quantitative studies that indicate the existence of general dynamic principles.

I. THE PROBLEM OF THE CLASSIFICATION OF SPEECH ENTITIES

The scientific study of speech may be said to have started millennia ago when, for the sake of devising a system of writing, man first began to concern himself with the classification of the stream of speech into its significant entities. The history of writing (cf. article on "Alphabet," *Encyclopedia Britannica*, 14th ed.), which is a part of the history of the psychology of language, reveals various more or less successful attempts in different regions to classify the local speech into its word elements, or its morphological elements, or its syllabic elements, or its phonetic elements, or even its morpho-semantic elements (e.g., Chinese). However, because the larger morphological, syllabic, and verbal elements of speech are intrinsically permutations of basic phonetic entities (e.g., *man* is a permutation of *m*, *a*, and *n*), the most practical classifications today are the alphabetic ones, of which the most extensive and accurate is the "narrow" *International Phonetic Alphabet* (of the International Phonetic Association). This alphabet classifies speech sounds essentially on an acoustic basis without concern about the particular phonetic differences in a given tongue that may be "significant" for that tongue in discriminating between its vocabulary of words.

As to the problem of determining "significant" phonetic differences within a given tongue, few solutions can compare with the simple method of *phonology* in the matter of operational neatness. This method consists of comparing pairs of words (i.e., *phonological*

oppositions) that are homophonous except for different phonetic entities, or *phonemes*, in analogous positions (e.g., *pin*, *pan*, *pun*, or *pin*, *sin*, *tin*). By studying the *phonological oppositions* of a given vocabulary of words, one can disclose the vocabulary's stock of different *phonemes* which may be appropriately defined as "the minimal phonetic units that are used in the vocabulary to discriminate between otherwise homophonous pairs of words." In many languages this *phonological technique* may leave a small residue of ambiguous items for which no *phonological oppositions* can be found. In the present writer's experience this residue is statistically negligible.

Although *phonologists* in recent years have added enormously to our descriptive knowledge of many different languages (a running bibliography of studies on the topic can be found in *American Speech*), and although the discovery of the phoneme has greatly simplified the transcription of speech, nevertheless some claims made by some phonologists would seem to be unwarranted if taken literally in a truly scientific sense. Thus despite claims to the contrary, it has never been shown that phonemes represent the minimal units of distinctive significance in any sense other than that of keeping phonological oppositions apart. Second, it has been shown by Eberhard and Kurt Zwirner ("Phonometrischer Beitrag zur Frage der neuhochdeutschen Quantität," *Archiv für vergleichende Phonetik*, I [1937], 96-113) that despite the assertions of some phonologists two different phonemes in a given speech are not always kept rigidly apart (e.g., the phoneme, short *ä*, in German which differs from long *ā* only in the matter of duration, is sometimes pronounced longer than is long *ā*; in point of fact the difference between the two phonemes is solely in their statistical modes).

II. THE GENETIC CLASSIFICATION OF SPEECH

Languages can also be classified on the basis of a common ancestry as ascertained by a comparison of forms and meanings. This work has long been conducted by *comparative philologists* (locally sometimes called *linguists*) who proceed on the basic assumption first empirically established by Karl Brugmann that *in a given language at a given time like phonetic entities under like conditions behave alike* (hereinafter referred to as the *orderliness of phonetic change*). For example, during a particular period

in Middle English all Old English words with a long *ā* became an open long *ō* which subsequently became the close long *ō* of today (e.g., Old English *stān*, *rāp*, *gāt* have become what we write today as *stone*, *rope*, *goat*). For most of the Indo-European languages, there are historical-comparative grammars and etymological dictionaries in abundance, of which perhaps the two best known are Karl Brugmann and B. Delbrück, *Grundriss der vergleichenden Grammatik der indogermanischen Sprachen*, 5 vols., 2nd ed. (Strassburg, 1897-1911), and Alois Walde and Julius Pokorny, *Vergleichendes Wörterbuch der indogermanischen Sprachen*, 3 vols. (Leipzig, 1927-1932). This vast store of carefully collected and objectively analyzed material has confirmed the principle of the *orderliness of phonetic change* beyond any doubt.

This principle is of practical value to the social psychologist in helping to disclose the date of adoption of foreign loan-words. Thus the fact that we pronounce the vowels of the Romance loan-words *dame* and *fame* like the vowels of *make* means that the two words were adopted in Middle English times *before* a certain phonetic change had occurred (cf. H. C. Wyld, *A Short History of English*, 3rd ed., New York, 1927). The fact that an initial *d* in Latin, such as in *duo*, two, or *decem*, ten, appears quite generally in even present-day English as a *t*, such as in *two*, two, and *ten*, ten, suggests (simply stated) that the words are not loan-words but *cognates* that have been inherited from a common ancestry with differences ascribable to independent phonetic changes that were peculiar to the histories of the respective languages.

III. DYNAMIC PRINCIPLES OF SPEECH

From the earliest days of history down to the present, man has produced speech-theories of varying degree of gravity of utterance that have not always been free from a suggestion of

"magic," even in the case of many of the *ad hoc* speech theories of comparative philologists. In recent years, however, the problem of speech-dynamics has been approached with increasing scientific rigor.

A. *The Dynamics of a Phonetic System.* The French psychologist, R. Bourdon (in his *Des Emotions et des Tendances dans le Langage*, Paris, 1892), was apparently the first to observe that in many different languages the dental stops (e.g., *t* and *d*) are more frequent than either the labial stops (e.g., *p* and *b*) or the velar stops (e.g., *k* and *g*).

Subsequently G. K. Zipf argued (i) that the comparative difficulty of utterance of a phoneme in a given speech-community was inversely related to the relative frequency of its occurrence, and (ii) that the orderliness of phonetic change results from the tendency to preserve or to restore a dynamic equilibrium between the difficulty of utterance of phonemes and their relative frequency of occurrence. Although this second argument (ii) is too extensive to be included here (cf. G. K. Zipf, *The Psychology of Language*, Boston, 1935), nevertheless the nature of the data and theory of the first argument (i) can be indicated quite simply:

Thus if we take, for example, the twelve consonantal stops of Peipingese Chinese which consist of the six *more difficult* aspirated stops, *tʰ*, *pʰ*, *kʰ*, *cʰ*, *ʃʰ*, *tʂʰ*, and the six *less difficult* corresponding unaspirated stops, *t*, *p*, *k*, *c*, *ʃ*, *tʂ*, we find in samples of 37,338 running phonemes (Zipf, *op. cit.*) that each of the six *more difficult* aspirated stops is markedly less frequent than its corresponding *less difficult* stop, as is shown by the percentages of frequency of the whole of Table I:

Although the above data refer only to six pairs of phonemes in one dialect, nevertheless the statistical analysis of the frequencies of other types of phonemes in other languages reveals the same correlation. Thus, for example, the *more*

TABLE I
VOICELESS ASPIRATED FORTES AND VOICELESS UNASPIRATED LENES STOPS IN
PRESENT-DAY PEIPINGESE

(Percentages in reference to occurrences of all speech-sounds)

	<i>tʰ/t</i>	<i>pʰ/p</i>	<i>kʰ/k</i>	<i>cʰ/c</i>	<i>ʃʃʰ/ʃ</i>	<i>tʂʰ/tʂ</i>
Aspirated (<i>more difficult</i>)	2.56%	.56%	1.02%	1.04%	1.23%	1.40%
Unaspirated (<i>less difficult</i>)	6.18%	2.37%	2.58%	2.69%	2.44%	2.63%

difficult long vowels in a given speech are almost without exception much less frequent than their *less difficult* corresponding short vowels (if they are present in the language). So, too, the *more difficult* voiced stops,¹ *d, b, g*, are

practically always much less frequent than their *less difficult* corresponding voiceless stops, *t, p, k*, as becomes evident from the percentages of the whole in the following dozen languages of Table II:

TABLE II
PERCENTAGE OF OCCURRENCES OF VOICED-VOICELESS STOPS
(Diphthongs counted as one unit)

	t	d	p	b	k	g
Czechish	5.60%	3.73%	3.52%	1.86%	3.93%	.15%
Dutch	7.83%	4.67%	1.99%	1.20%	3.21%*	.09%*
English	7.13%	4.31%	2.04%	1.81%	2.71%	.74%
Hungarian	7.18%	3.30%	1.04%	1.71%	5.72%	2.45%
Lithuanian	5.76%	2.61%	3.71%	1.35%	4.61%	1.36%
North Russian	7.97%	1.52%	3.36%	1.01%	3.36%	.67%
South Russian	7.05%	2.46%	2.79%	1.51%	3.97%	1.66%
Wendish	6.26%	3.02%	2.55%	1.56%	3.29%	2.41%
East Ukrainian	3.83%	3.24%	2.82%	2.11%	4.11%	not present
Bulgarian	7.54%	3.55%	2.82%	1.32%	2.98%	1.46%
Greek	7.58%	2.87%	3.38%	.49%	4.07%	1.74%
Sanskrit	6.65%	2.85%	2.46%	.46%	1.99%	.82%

* Variphone.

Studies of this type, which have been carried on extensively, show that the entities of a phonetic system behave as a system in which dynamic equilibrium is preserved between frequency and difficulty of utterance. In this connection it should be pointed out that in a brilliant study of the errors made by deaf mutes in pronouncing different phonemes, C. V. Hudgins and F. C. Numbers ("An Investigation of the Intelligibility of the Speech of the Deaf," *Genetic Psychology Monographs*, XXV [1942], 289-392) have shown (363 f.) experimentally that the errors in articulating phonemes *increase* as the relative frequencies of the phonemes *decrease* (the correlation being .88, P.E. .02 for consonants, and .92, P.E. .01 for vowels)—thereby establishing a "pragmatic scale of difficulty" which is inversely related to frequency of occurrence.

Such few experimental and statistical studies in phonetics (cf. bibliography in *American*

Speech) as are cast in dynamic terms attest to the thoroughgoing orderliness of the phonetic process.

B. *The Generalized Law of Abbreviation.* The above inverse relationship between the comparative difficulty of articulation and the relative frequency of occurrence is not restricted to phonemes. On the contrary it is a conspicuous feature of all the entities of the speech-process.

Thus, when in a given language there are differences in the amount of stress-accent, whether between words in a sentence (e.g., *a man*), or between the roots and affixes within words (e.g., *under-stand-ing*), there is a marked tendency for the entities of comparatively lesser stress-accent to be coupled with a greater relative frequency of occurrence, although other factors are not absent (cf. Zipf, *Psycho-Biology*, *op. cit.*, Chap. 4).

So, too, in respect of the comparative lengths of words (*ibid.*, Chap. 2), or of their morphological parts (*ibid.*, Chap. 4), there is an unmistakable inverse relationship between length and frequency of usage which according to the research of E. L. Thorndike ("Studies in the Psychology of Language," *Arch. of Psych.*, No. 231, Sept., 1938, 67) applies even to words

¹ For experimental support of this statement of greater difficulty, cf. C. V. Hudgins and R. H. Stetson, "Voicing of Consonants by Depression of Larynx," *Archives Néerlandaises de Phonétique Expérimentale*, XI (1935), 1-28. For the statistics on these voiced and voiceless stops, cf. Zipf and Rogers, *ibid.*, XV (1939), 111-147, also Zipf, *Psycho-Biology*, *op. cit.*

whose frequencies are less than two in a million. As to the mechanisms whereby this inverse relationship is preserved, Zipf has argued (*Psychobiology, op. cit.*) that truncations of form (e.g., *gas* for *gasoline*, or *phone* for *telephone*) and substitutions of short words for long ones (e.g., *car* for *automobile*, or *current* for *electricity*) play an important role.

Whether the above inverse relationship between length and frequency (the Law of Abbreviation) applies also to the lengths and frequencies of phrases, clauses, sentences, and so on, has never been empirically tested. Nevertheless, A. C. Norwine and O. J. Murphy ("Characteristic Time Intervals in Telephonic Conversation," *Bell Telephone System Technical Publications, Monograph B-1074*, also in *The Bell System Technical Journal*, XVII [1938], 281-291) have shown that in telephone conversations the short "utterances" or "talk-spurts" are much more abundant than the longer ones with frequency rapidly decreasing as the size of the utterance increases. Eliot D. Chapple has confirmed this finding in his studies of non-telephonic conversations, and has further found, as we shall presently see, that there is a logarithmic linear relationship between the lengths and frequencies of a person's utterances and silences during his conversations ("Personality Differences as Described by Invariant Properties of Individuals in Interaction," *Proc. National Academy of Sciences*, XXVI [1940], 10-16).

C. *The Effect of Analogy.* Of particular interest to students of human behavior is the phenomenon of analogic action where a particular act of one class, say *a*, which has certain characteristics of another class, say *b*, alters its behavior so as to conform completely to the criteria of class *b*. The phenomenon of analogy is both frequent and transparent in speech. Thus, though we are taught in school that the plural of *ox* is made by adding *-en* to *oxen* (class *a*), whereas the plural of most other nouns is made by adding *(e)s*, as in the case of *boxes*, *foxes*, *cats*, *dogs*, *houses* (class *b*), nevertheless we frequently hear the plural *oxes*, apparently out of respect for what is the plural-pattern in the overwhelming majority of nouns. Expressed as a ratio, we may say that *ox:oxes::box:boxes*. The same argument applies to the past tense of *to dive*, which today is *dived* (out of respect for the prevailing pattern) instead of the older *dove*. There are also cases of analogic changes

in accentual and phonetic structure (Zipf, *Psychobiology, op. cit.*, Chaps. 3 and 4); and so too in the syntax of phrases (e.g., the more traditional *different from* becomes *different than*, presumably in analogy with *other than*).

In the analogic changes of speech we see perhaps the economy of reducing the number of different classes, or "stereotypes," in terms of which speech-action occurs.

D. *The Frequency-Distribution of Words.* In studying stenographic problems, J. B. Estoup (*Gammes Sténographiques*, 4th ed., Paris, 1916) observed the general hyperbolic relationship between the number of new and different words in successive samples of a thousand French running words on the one hand, and the cumulative diversity of vocabulary on the other. Since then innumerable frequency studies have been made.

In 1928, E. V. Condon ("Statistics of Vocabulary," *Science*, LXVII [1928], 300) presented graphically the frequency-distribution of the *n* different words in a large sample of speech, ranked in the order of decreasing frequency. In this he found that the *r*-rank of a word, when multiplied by its *f*-frequency of occurrence, approximated the equation $r \times f = C$. In Figure I we find two examples of this distribution, with *r* measured logarithmically on the abscissa and *f* logarithmically on the ordinate for (I) the vocabulary of James Joyce's *Ulysses* (M. L. Hanley, *Word Index to James Joyce's Ulysses*, Madison, Wis., 1937), and (II) the 43,989 running words of samples of American newspapers according to R. C. Eldridge (*Six Thousand Common English Words*, Buffalo, 1911).

However, if we consider the curves of Figure I as particular cases where $p = 1$ of the generalized harmonic series:

$$F.S_n = \frac{F}{1^p} + \frac{F}{2^p} + \frac{F}{3^p} + \dots + \frac{F}{n^p}$$

in which the denominators refer to the respective ranks of the *n* different words in the sample (and where $F = n^p$), we have a more useful equation in mathematically describing a "saturated" sample of approximately *F.S_n* running words. Thus, in the polysynthetic American In-

² Zipf's subsequent and independent observation that the *N*-number of different words of like *f*-frequency under certain conditions approximates the equation $N \times f^2 = C$ is corollary to the above (cf. *Psych. Record*, II [1938], 347-367).

FIGURE I

dian languages of *Nootka*, etc., Zipf has observed values of p that are less than 1.³ J. C. Whitehorn and Zipf ("Schizophrenic Language," *Arch. Neur. and Psychiatry*, XLIX [1943], 831-851) have observed a value of p greater than 1 in the letters of a female paranoid schizophrenic—a finding that was subsequently confirmed independently by Dr. James J. Miller in his hitherto unpublished study of the conversation of a schizophrenic patient. Nor is this observation inconsistent with S. W. Cook's and B. F. Skinner's study of certain verbal association data of the insane ("Some Factors Influencing the Distribution of Associated Words," *Psych. Record*, III [1939], 178-184).

As to the size of n (and Sn) in the above

equation Zipf has noted in his studies of children's speech (preliminary report, *Science*, XCVI [1942], 344-345; complete report to appear in *The Principle of Least Effort*) that there is a positive correlation between n (and Sn) and the chronological age of the child, as is to be expected.

But although the above equation of the generalized harmonic series may be of great descriptive value, it can scarcely be the primary equation since it tells us nothing about the length of the intervals, I , between the repetition of words, a problem whose preliminary exploration was kindly undertaken by my former seminar student, Dr. Alexander Murray Fowler, and later extended and published with detailed theoretical and mathematical treatment (G. K. Zipf, "The Repetition of Words, Time-Perspective,

³To be reported in his forthcoming book, *The Principle of Least Effort*.

Order of Interval in Time

FIGURE II

and Semantic Balance," *Jour. General Psych.*, XXXII [1945], 127-148, with 28-item bibliography). According to the data of the Hanley word-index to Joyce's *Ulysses* (*op. cit.*), the N number of different I_f intervals of like length (in pages) between the $f - 1$ repetitions of all words in the *Ulysses* of like f -frequency approximates the simple equation:

$$N \cdot I_f = a \text{ constant.}$$

As a typical example of this distribution we find in Figure II the actual data for the I_{24} -intervals between the repetitions of all the 34 different words occurring 24 times in the *Ulysses*; arithmetically on the abscissa are noted the 23 (i.e., $f - 1$) successive intervals, and logarithmically on the ordinate are indicated with crosses the I interval-sizes in pages for the 782 (i.e., 34×23) different intervals between repetitions. An inspection of this scatter-diagram reveals not only that the I -intervals of varying lengths are distributed quite evenly over the entire book, but also, and even more significantly, that they are similarly distributed in each of the successive intervals. Zipf has argued (*ibid.*) that this indicates the even distribution of minimalized work over time, and that the foregoing equation is primary to the others which are corollary to it.

E. *The Problem of Distributing the "Meanings" of Words.* Inasmuch as words are used to convey "meanings" (i.e., to evoke more or less stereotyped responses in the interlocutor) the question presents itself as to what these clear-cut linear word-frequency distributions may indicate about the distribution of different "meanings" among the words. Although the theoretical problem is too extensive to discuss here,⁴ Zipf deduced theoretically that the m_f number of different "meanings" of a word of f -frequency would tend to approximate the square root of f , or:

$$m_f = f^{\frac{1}{2}}$$

For the purpose of testing this theoretical equation Zipf, with the help of his students, ascertained from the data of the *Thorndike-Century Senior Dictionary* the average m -number of different living meanings per word (according to the Lorge-Thorndike semantic count, cf. *ibid.* preface) for the twenty successive sets of thousand most frequent words of the E. L. Thorndike list of 20,000 most frequent English words (E. L. Thorndike, *A Teachers Word*

⁴ Cf. G. K. Zipf, "The Meaning-Frequency Relationship of Words," *Jour. Gen. Psych.*, XXXIII (1945), 251-256. To be treated more fully in *The Principle of Least Effort*.

FIGURE III

Book of the Twenty Thousand Words, etc., revised, New York, 1932).

The results of this investigation are presented graphically in Figure III, with the ranked thousands of words measured logarithmically on the abscissa, and with the average meanings per word measured logarithmically on the ordinate. By least squares these points of Figure III have a negative slope of .4605 ($\pm .0083$). And if we may assume that the rank-frequency distribution of the underlying words would approximate the equation of the generalized harmonic series with $p = 1$, then we may say that these data can be approximately described as

$$m_f = f^{.4605}$$

In any event the linearity of the data of Figure III, which far surpasses even the fondest hopes of the present writer, shows that there is indeed a law of word-meaning distribution.

F. *Summary of General Speech-Dynamics.* Although the foregoing data represent only a small sample of the present-day resources of statistical findings, nevertheless they suffice to show that the speech-process is dynamically structured according to fundamental principles that apparently operate quite generally with extreme rigor. And that seems to be the case whether we view the sizes and frequencies of usage of words, or their rate of repetition, or their respective "loadings" with "meanings," or the phonetic minutiae of which they consist. Since it is difficult to imagine that the speech-process is not completely integrated with the rest of the personality and with human social relations, these findings would seem to impose important restrictions upon all theories of the personality and of human relations.

IV. STYLE AND PERSONALITY INVARIANTS

Each person's speech is to some extent characteristic of him, whether because of its tone, timbre, and the like, or because of his choice and arrangement of words and the speed with which he talks, or because of his general loquacity or taciturnity—or because of a combination of all these. And to some extent a person's written style may be characteristic of him. Indeed, since earliest times, holy men have scrupulously guarded the *precise* structure of sacred texts, while the reconstruction of the *original* texts of past authors has provided a livelihood for innumerable philologists who

have also not hesitated to ascribe texts to one author or another on the basis of generally subjective criteria of style (though sometimes they may naïvely strive to be objective). Perhaps the most articulated of these subjective (or quasi-objective) tests of style is that of E. Sievers (*Ziele und Wege der Schallanalyse*, Heidelberg, 1924), which, though no longer in vogue today, is nevertheless typical of the "Pentecostal" (or "Whitsuntide") methods of analysis that are employed in such problems by European and American experts in the humanities today.

In the meantime, however, with the general advance of scientific interest, clear thinkers, unencumbered by the "Pentecostal" traditions of linguistics and the humanities, have turned with considerable success to the problem of the characteristics of individual speech style.

Thus, in 1938, G. Udny Yule published ("On Sentence-Length as a Statistical Characteristic of Style in Prose; with Application to Two Cases of Disputed Authorship," *Biometrika*, XXX [1939], 363-390) his quantitative investigation of sentence-length as a statistical characteristic of style in prose. Dividing sentence-lengths into classes of 1-5 words, 6-10, 11-15, and so on, Yule analyzed two sizable samples each from Bacon's *Essays*, Coleridge's *Biographica Literaria*, Macaulay's *Essays*, and Lamb's *Elia* and *Last Essays of Elia*. In each case he observed that the two samples from the same author agreed fairly closely, while differing from those of other authors. He then applied his technique to writings of disputed authorship.

In 1944, Yule reported (*Statistical Study of Literary Vocabulary*, Cambridge, England, 1944) the results of his statistical analysis of the diversity and frequency of nouns in several authors. Despite the admitted incompleteness of Yule's work, which may have resulted to some extent from Yule's strange unawareness (p. 32) that anyone else had compiled and studied word distributions,⁵ the analysis itself is of great didactic value both for its statement of statistical problems related to the topic and for its application of statistical methods to some of those problems.

A study of alliteration and of certain types

⁵ For a fairly complete bibliography of the now enormous literature on word-frequency distributions, cf. C. C. Fries and A. A. Travers, *English Word Lists*, American Council of Education, Washington, D. C., 1940.

of sound-patterning in poetry by B. F. Skinner ("A Quantitative Estimate of Certain Types of Sound-Patterning in Poetry," *Amer. Jour. of Psych.*, LIV [1941], 64-79) has also yielded interesting results—though partly of the nature of a negative proof—and is of considerable value in helping to state objectively the entire problem of literary and stylistic criticism. Moreover, B. F. Skinner's invention of the verbal summator ("The Verbal Summator and a Method for the Study of Latent Speech," *Jour. of Psych.*, II [1936], 71-107), together with W. K. Estes' invention of the visual form of the summator ("A Visual Form of the Verbal Summator," *Psych. Record*, IV [1940], 174-180), offer distinct possibilities of studying quantitatively a person's own verbal associations, which, more than anything else, would seem to be peculiar to his personality.

As far as the diversity of a person's vocabulary is concerned—a topic inferentially broached by Estoup (*op. cit.*) and latterly treated in respect of nouns by G. U. Yule in his recent book (*op. cit.*)—J. B. Carroll, who has studied the problem both quantitatively and theoretically with great care, believes: "An index of diversity might also be used to differentiate linguistic materials with respect to stylistic and other characteristics." (J. B. Carroll, "Diversity of Vocabulary and the Harmonic Series Law of Word-Frequency Distribution," *Psych. Record*, II [1938], 379-386.) Carroll's equation for vocabulary diversity would seem to be of considerable practical value (if, as he points out, the equation of the harmonic series is known to apply to the entire sample).

Addressing himself to the topic of speech and the personality, F. H. Sanford restricted his investigation to a comparative study of the speech-action of two young men, and is able to report on the basis of extensive and scrupulously detailed data (F. H. Sanford, "Speech and the Personality: A Comparative Case Study," *Character and Personality*, X [1942], 169-198): "By means of 234 'mechanical,' grammatical, 'psychogrammatical,' and lexical categories, samples of oral speech from two subjects were subjected to an intensive statistical analysis. The quantitative data yielded by this analysis lend themselves to conceptualization in terms of linguistic traits, one group of traits for one subject, another group for the other."

At about the same time the above studies were undertaken, Eliot D. Chapple, likewise working independently, studied the ratio of an individual's speech-actions to his speech-silences in conversations. Chapple discovered (*op. cit.*, p. 15): "The measurement of the interaction of individuals provides us with an opportunity to find out whether any unique property of an individual, ordinarily called 'personality,' manifests itself when two people are talking together. When a series of observations is made, the frequency distributions of the durations of actions and silences are fitted to the exponential equation, $F = ae^{-bt} + ce^{-dt}$, and the plot of $\log b_0/b_s = -\log d_0/d_s$ with a slope of 1." (I.e., of -1, *ed. note.*) "The position of this curve as defined by the intercepts is invariant for each individual, since it does not shift when the individual interacts with different individuals. The range of the curve also may be invariant for each individual, being delimited at the lower end by the absence of a d silence slope and at the upper end by the absence of a d action curve. These invariant properties afford us a quantitative description of individual differences in 'personality' as exhibited in the rates of acting and being silent in interaction."

Although in the present writer's opinion the above Chapple observation is of enormous theoretical value in understanding the economy of mentation, it should be pointed out that Dr. Chapple has also found his methods of great practical value in the entire field of the diagnosis of personality disorders (cf. E. D. Chapple and Erich Lindemann, "Clinical Implications of Measurements of Interaction Rates in Psychiatric Interviews," *Applied Anthropology*, I [1942], No. 2, 1-11).

In addition to the foregoing studies there are many others for specialized fields, such as that of Mary Shattuck Fisher for children's speech ("Language Patterns of Preschool Children," *Child Development Monograph*, No. 15, Teachers College, New York, 1934). The problems of reading and spelling are quite properly fields in the general psychology of language. These will be found abstracted in the *Psychological Abstracts*. For the entire field up to 1936, including also the largely subjective treatises, there is an excellent critical bibliography by Donald V. McGranahan ("The Psychology of Language," *Psych. Bulletin*, XXXIII [1936], 178-216). For

additional bibliography and discussion see J. Eisonson, *The Psychology of Speech*, New York, 1938.

V. GEOGRAPHICAL AND SOCIO-ECONOMIC ASPECTS OF SPEECH

In addition to the internal dynamics of speech and their peculiar manifestations in the speech of different persons, there are also geographical and socio-economic factors in speech that may be of considerable importance to social psychology.

A. *Dialect Geography*. A native of New Orleans in talking to a native of Chicago, Boston, or New York will unwittingly inform the latter of his place of origin, because of his peculiar "accent." This relationship between a person's accent and his regional origin has long been noted and during the past century has evoked the ever-growing interest of specialists in the field of dialect geography (for an excellent account see L. Bloomfield, *Language*, New York, 1933, Chap. 19; for a fairly complete annual bibliography of articles consult *Indogermanisches Jahrbuch*, Strassburg-Berlin, annually since 1914). The chief weakness of dialect geography to date, as far as dynamic social structure is concerned, is its tendency—unlike present-day geography—to ignore the research in the growing field of demography (for a bibliography of demography see the quarterly *Population Index* of the Population Association of America).

B. *Speech as Socio-economic Cues*. It has perhaps always been known that a person's speech tends to reveal a person's social-economic class-origin (cf. G. B. Shaw's *Pygmalion*). In this sense a person's speech may be viewed as consisting in part of what can appropriately be termed *socio-economic cues*. This problem has been approached with the broadest possible perspective in the penetrating study of trait-names by G. W. Allport and H. S. Odbert ("Trait-names," *Psych. Monographs*, No. 211, 1936), whose discussion (pp. 1-37) of the entire problem of the verbal labelling of the "other fellow's" traits of disposition may be viewed as a classic introduction to the field. But as to the narrower topic of correlating particular traits as cues to membership in particular socio-economic groups, investigation still lags.

GEORGE KINGSLEY ZIPF,
Harvard University

LEARNING.—The problem of learning is one of the most important in the whole field of psychology, because all human behavior, on whatever level and under whatever circumstances, involves learning of one kind or another. It is clear from this statement that we are making the meaning of the term learning more or less equivalent to the meaning of such words as change, modification, growth, development and adjustment. To be sure, these words have, in addition to their general meaning, specific implications, but any organism, at any stage of its evolution, is not only in an environment but is being acted upon by that environment and reacting in turn to it. And all such action-reaction behavior involves changes and modifications of the organism as well as, in some instances, changes in the environment.

These statements hold true regardless of what position we take as regards endowment or heredity. Whether we conceive of the organism from the moment of birth or from the moment of conception, the general statements of the first paragraph hold true. We shall not, in this article, be concerned with the problem of heredity, but rather, as is clear from the title, with the general problem of learning. It is also evident that change, modification, or learning take place in the action and reaction of the organism and the environment, whether such change is intentional, deliberate, and controlled, or haphazard, uncontrolled, and without intent. Some writers are wont to use the term learning only in deliberately controlled situations, but the modifications and changes that take place without intent are often even more productive of major shifts in the organism, in its relation to the environment, than the specifically deliberate modifications.

The same general principles are involved when a student sits down to learn how to extract cube root or when that same student inadvertently and unwittingly acquires at some period in his life a fear of cats or of the dark. Furthermore, the same principles of learning are involved when a cat learns to get out of a box, a rat to run a maze, a child to tie or untie his shoe-laces, or an adult to give a public speech. In short, learning may involve modifications of a motor nature, a verbal nature, an emotional nature, or as is most frequently the

case, a combination of these aspects of behavior.

We may look at the whole problem from still another general point of view before going more into detail. As we look at the organism it is clear that the very term organism implies an environment; neither one can exist without the other. The organism, for its part, is equipped through its early growth *in utero* with two sets of so-called receptors. First, the external receptors such as the eye, the ear, and the skin which are literally energy-catching devices directly in contact with the environment where energy of various sorts is constantly being given off. These receptors react to this energy, pass it on through the connector system whence, in turn, it passes on to muscles that then move the organism in the environment, modify the environment, result in a speech reaction, or some combination of these. The channels through which this energy passes from the environment through the organism and thence back to the environment are not pre-established by any specific endowment or hereditary influences. On the contrary, as we know, early energy-impacts on the organism tend to flow out widely and indiscriminately resulting in diffuse rather than particularly adjustable behavior. Nonetheless, such non-adaptive channels as are thus used become the basis for the later refinements and specificity of exact adjustment.

It is true, secondly, that there are interior receptors which are acted upon by the physical and biochemical energies of the organism, which energies like those originating externally, find their way out through channels that ultimately involve either movements of the organism in the environment, modifications of the environment, or modifications of the set and condition of the organism itself, interiorly. It is also true that some energy-impingements from the external environment result in interior modifications of the organism itself. This is, of course, the field of psycho-somatic changes so that we can say, for example, that we learn to have a tachycardia or to so modify the internal coats of the stomach that an x-ray will reveal that we have literally learned to have ulcers.

This particular article goes on the assumption that learning is then a modification due to the energies of the organism and the environment impinging on the organism itself. To be more explicit, every stimulus, that is, every

sufficient item of energy impinging on the organism from within or without, must lead to some behavior-reaction, internal or external. If the energy is sufficient to trip off a receptor, that energy cannot be stored or rejected, but must find exit in some effector-apparatus, either internal or external or both. Not only can energy not be stored or inhibited in its transit through the body, but it is also evident that there are no immutable or predestined requirements as to what the behavior-response or final energy manifestation will be. In short, any stimulus, internal or external, depending on the previous experiences and the present condition of the organism, can result in any response. And it is just these energy intakes and outputs which bring about those more or less permanent changes in the organism and particularly in the connector system which constitute learning.

Learning, in short, is the making of connections or circuits between receptors and effectors. All learning is, therefore, subject to further modification and learning, so that one can say not only that an old dog can learn new tricks, but that no previously established circuit or behavior-response is immune to further modification. It is probably true that, once a circuit is established, in some sense it remains integral, apart at least from ravages of disease or physical damage. But this does not mean that adjuncts and modifications cannot be joined to any given pattern of learning, or that a so-to-speak parallel form of response cannot be also established.

The relatively simple statements of the above paragraphs should not be taken too simply or too narrowly. As a matter of fact, which common observation sustains, seldom if ever do we respond to one simple energy in-put or stimulus with one simple energy output or response. As the organism gets older and older it responds more and more to a cluster of stimuli or a complex situation with a cluster of responses or an adjustable act. But it is always possible, in moments of extreme danger or in situations of unexpected violence, to revert to earlier and simpler stimulus-response reactions. This means that the relation of the organism and environment, taking into account both internal and external receptors, and internal and external effectors, is an extraordinarily fluid and complex sort of thing, which can be viewed now statically and academically in cross-section, but

which is in reality a fluid, growing, changing, integrating affair.

In all the above, certain dynamic principles are, of course, implicit. With reference to our statement of the organism-environment relationship, it must be further said that while there is a fluid and dynamic there is also, nonetheless, a deterministic relationship. An organism from the point of view of learning or of expressing previous learning, is in no sense able to act without a stimulus, internal or external, and it can only act in terms of all the factors involved. The organism, in short, is an energy-gathering, energy-sorting, and energy-delivering mechanism, if by mechanism we do not mean something set and fixed in make-up and capacities. The young organism, prior to or just subsequent to birth, is much more subject to the crude push and pull of the environment than is an older organism which has acquired specific patterns of response due to the effects of living in previous environments. But this dependability upon the environment for stimulus and growth is merely one side of the problem. There is also the growth and modification of the organism itself which, though they are a function of previous experiences, come to have a more and more cumulative and decisive effect in total behavior. We can never escape the environment, but if our previous learning has been adequate, we shall be able to respond with greater and greater adequacy from the point of view of the welfare of the organism.

The organism, therefore, registers within itself previous environments in the form of neural patterns of response and, like the chambered nautilus, can build itself, within the limits of any given environment, more and more facile and more and more intricate adjustive patterns, until the day comes when the organism, as such, begins to decline, loses its flexibility and learning capacity, and becomes once more subject in greater degree to the push and pull of the environment. The organism is born very ineffectual, requiring much care and guardianship, learns much directly and indirectly, adjusts itself more and more cogently, takes into account more and more of the colorings and shades and details of the environment, until it loses its capacity for further learning due to decay of tissue. Much of this learning and modification, as we have already pointed out, is unforeseen, unintended, and just happens.

Some of it is deliberate and intended, either under the directorship of teachers or parents, or of purposes and plans which have previously been instilled. The organism, therefore, is constantly in a delicate state of balance, striving on the one hand to obtain what it needs and finds pleasure in and, on the other hand, striving to avoid what interferes with its needs, upsets its balance, and gives it pain and dissatisfaction.

In terms of the general statements of the above several paragraphs we must re-emphasize and distinguish several different aspects of a stimulus situation. First of all, there are internal stimuli originating in tissue conditions which lead to overt and observable behavior. But it is also true that in a wider sense, external conditions of temperature and the like, so affect the body that these internal tissue conditions are literally touched off by the environment. Secondly, of course, external conditions can bring about external responses. Some of these responses are directed primarily toward altering the environment, and still other responses are directed toward modifying the condition of the organism itself through manipulation of the environment. The tissue conditions themselves we have called "drives," and the behavior which modifies the tissue conditions and satisfies them through use of the environment we call "mechanisms." It is also clear that, through conditioning and learning, the whole situation becomes extraordinarily complex, so that mechanisms which have been previously associated with the satisfying of a given drive, may themselves become satisfying in their functioning apart from the actual operation of a drive. Thus play and exercise are, so to speak, self-sufficient and self-supporting mechanisms which originated as simpler exploration and manipulation of the environment, thus serving as a mechanism directly in terms of a drive. Any habit is, in some sense, a mechanism, but it may achieve an independence and become satisfying in itself apart from its specific origin. In short, all behavior is a function of the condition of the organism in relation to that of the environment, with a constant shift of emphasis to the inner and outer conditions.

We have already mentioned internal receptors which are stimulated by the condition of the surrounding tissues in which they lie. They constitute, as we have said, so-called drives. Take, for example, hunger in a young child or

other animal, such as a dog. Shortly subsequent to birth, since the organism is in an environment of lower temperature than the body itself, and since random movements caused by internal or external stimuli will use up energy and blood sugar, tissue changes of a very complex nature take place. Unless these tissue changes are in some sense restored to normal, the organism will perish. But the young organism has no conception or understanding of this total and complicated state of affairs. The tissue changes in question simply stimulate and energize the receptors that are adjacent, and the receptors, in turn, pass on the energy to the connector system and thence by diffusion to effectors external or internal. This, in a very young animal, results in whines, cries, writhings, as part of the total diffused reaction. An older animal, through previous experience, recognizes these responses to an internal state of affairs, and attends to the young organism. Thus certain cries and actions are at one and the same time a signal to the older animal, and a so-called mechanism in the process of being formed or learned on the part of the younger organism. By and by, through various further stimulus-response achievements, ever greater specificity of learning occurs on the part of the young organism, and the child will say "food" when hungry. This is learning, i.e., forming a specific response pattern to a stimulus.

Consider as a similar but more complex example a somewhat older dog or child when it becomes hungry. Let us assume here that motor co-ordination has proceeded much further, that the animal is able to wander around but is yet without much understanding or comprehension. It is still responding in large measure to the released energy of its internal receptors, and it would not be accurate, at this early state of affairs, to say that the animal is deliberately and actually seeking food. On the contrary, it is acting still more or less at random, in terms of internal drives and tissue conditions. If, in the course of such semi-random motor movements, it finds food under a cluster of circumstances of sight, sound, and odor, it may again under similar internal conditions wander in the same direction and find the same satisfaction.

Learning is here definitely progressive. But, be it noted, that however simple or however complex the behavior involved, it is in response in the instances given, to a stimulus arising

from a state of the organism. Mechanisms or methods of satisfying such an internal state of affairs may become very complex and involve all sorts of fortuitous and irrelevant conditions of satisfaction. From this point of view we may say, still having in mind internal organic states, that however complex and sophisticated behavior seems, it involves at least in part just such simple drives or tissue conditions, though the external complications of the observed act may at first sight hide their basis.

The above stresses the organic aspect of learning, but we have also pointed out that the organism always lives in and learns in terms of the factors of the environment. Therefore, external stimuli also play a part in learning. The environment may very much restrict a given drive, exaggerate or distort it, so that one child may exhibit many food and feeding difficulties and even become definitely ill because of them, while another will, for reasons that are discernible upon analysis but often lost to the observation of everyday living, become very eccentric and refuse to eat any but a very limited and insufficient number of foods. And yet each such problem is due to a tremendously complex organization of organic and environmental stimuli and situations. In short, we have here an instance again of our former statement that any stimulus can be joined to any response, whether the responses or the stimuli are internal or external.

Can any sense be made of this tremendously complex situation? Are there any rules or principles that can be discerned which will make all such examples of the modification of behavior subject to clear understanding? In short, are there really any laws of learning that will apply to every instance of growth, development, and modification?

Let us take several further instances of behavior involving learning, that is, modification, at different levels of complexity, which will show the interaction of external and internal stimuli. Consider a mature man or woman striving to improve his score and efficiency in golf or tennis. There may or may not be a critic, guide, and teacher. But, in any case, it is clear that there is an intent or purpose, that there is practice, trial and error, and that there is improvement; at least, if there is not actual improvement, there is an intensification of greater assurance of a given level of skill. This is cer-

tainly learning, and there is certainly present an interest or drive. It may be directly economic, that is, relating to food, if it is a professional involved who is living by his skill. Also it is apparent, again by direct observation, that there is trial and practice, and it is likewise apparent that there is dissatisfaction when success or learning does not occur, and satisfaction when it does. But all this, as we have remarked, is at a highly conscious and deliberate level of behavior.

Secondly, let us consider a cat or other animal confined in a box or basket, egress from which can be had only if the animal, let us suppose, pulls a little ring hanging in one of the outer corners. Here, most certainly, there is no verbal statement of intent or purpose on the part of the animal to get out of the box, and we, the experimenters, cannot by talking to the animal arouse any such intent or purpose. Nonetheless, the cat will either get out of the basket or at least try to. So that, once more, we may say that the cat will either learn or at least try to learn. The first thing we notice in such a situation is that unless the cat becomes in some sense motivated, that is, unless a drive becomes operative, its behavior will be more or less non-adjustive. It may just lie down or wash its face. But suppose that we so control the environment that a drive does become operative. We can do this by placing a piece of fish within the range of olfactory receptivity. We shall then, provided the cat is hungry, notice a change in its behavior. Like the golfer mentioned above, he will react in terms of the drive, and the internal stimulus from the tissue condition will lead the cat to indulge in all sorts of diffuse and random behavior. It will claw the walls and the floor, brush against the sides, roll over, complain with plaintive meows or yowls. It will, in short, indulge in trial and error, though to be sure it is, at first, mostly error. Let us further assume that in the course of such random behavior, as is indeed easily observable in the laboratory, the cat does by chance pull the string attached to the ring. Up flies the lid, out goes the cat, down goes the fish. Now, whether the cat knows it or not, it has formed the beginning of a new pattern of adjustive behavior, but as yet it is not clear just how this has happened. But it is perfectly evident on observation that the cat which has gotten out once, by mere chance, will get out a little sooner if it is placed in the same situ-

ation, the same drive occurring, and the same reward following the successful effort. By and by, no sooner is the cat placed in the basket, than it can and will if a drive operates, get out.

This is perhaps an even better example than that of the golfer or tennis player because it is at a much simpler level. The whole problem is uncontaminated by remarks on the part of the experimenter, such as, "Do it this way"; "Don't do this"; "Keep this in mind"; and the like. And in all probability, it is also uncontaminated by any such reflections or verbalizations on the part of the cat itself. Let us consider also a modification of this experiment. Suppose we put a cat in the situation we have described and each time, from the very first, that it pulls the string and pops its head out, we slap it and push it back. It certainly is clear that it would require a very heroically hungry cat to persist in trying to learn how to get out. On the contrary, it would learn to stay put and just express an increasing degree of organic activity and irritability.

Consider still a third and different example. Let us suppose that a child is seated in a favorite chair at the breakfast table, eating its favorite food, surrounded by all its Lares and Penates in the form of family members, teddy bears, and the like. The child is hungry and is learning, as it has learned on previous mornings, to handle a spoon and glass without slopping or dropping things. Suddenly the experimenter approaches from behind the child and drops an excited rabbit, splash, in the bowl of breakfast food. It would be an extraordinary child who would not burst into tears, stop eating, and go into more or less random and diffuse behavior.

The next morning, let us say, when Johnny comes to the table to eat his breakfast the rabbit is visible either in someone's arms or in a cage on the other side of the table. It would, again, be an extraordinary child who would just placidly continue to eat his breakfast. In other words, the child has learned through experience to be afraid of and to be inhibited by a rabbit. That is to say, one experience has made some change in the connector system, so that the child is more or less permanently different as a result of the experience. And certainly no amount of verbalization on the part either of the child or the parents will wipe out this experience, though, of course, further learning can result in a continuance of more or less normal

breakfast behavior. Here, too, a drive was involved, an experience occurred in connection with it which, though it was merely a single experience, was in effect the practice that brought about the resultant change.

Let us take still another example. Suppose that a dog is hungry and is actually smelling though not yet eating its dinner. We observe, furthermore, that the dog is drooling at the mouth as partial evidence of the involvement of its digestive system in terms of previous experience. While it is thus drooling, we ring a given bell, and while it is ringing we feed the dog. We do this several times, always under more or less the same circumstances. By and by we find that the ringing of the bell just by itself is sufficient to cause the animal to drool. This, too, is learning because the animal is now responding in the way it originally responded to the odor and sight, to a new auditory and experimentally introduced stimulus, namely, the sound of a bell. There are many modifications of this particular experiment in which the bell can be sounded during or at a stated interval before the feeding, and it is again clear that a drive is involved, practice and experience are involved, and satisfaction is involved. For it is apparent, from further experiment that no dog will keep on drooling indefinitely in response to the sound of a bell if it is not fed shortly subsequent to such a stimulus.

Now whether we call our example of the golf player conscious and deliberate learning, and that of the cat forced, experimental, and controlled learning, and, on the other hand, call the instance of the child and the rabbit an emotional shock conditioning, and the dog and the bell a biological, unintentional conditioning, makes no difference. They are all simply different varieties of learning in terms of our definition of learning; namely, that learning is modification of behavior brought about by the action and reaction of the organism and its needs with the environment and its forces. Depending on circumstances involved in the immediate experiment and the past experience resident in the organism, the golfer may continue to improve, go into a slump, or give up the game entirely. The cat may continue to be able, even after a long period of time has elapsed, to get out of the problem box, or he may quickly "lose" the ability he has learned. In any case, we know from further experiment, that what

has once been learned has made some sort of a permanent trace or difference in the nervous system, because we find that a person or animal who has once become proficient in a given situation, and then over a period of time become less so, can recover the former level of efficiency much more quickly than another person or animal that has not had the training in question can reach that level.

As for the child and the rabbit, other circumstances, not our immediate concern, will determine whether the one shock experience will die out, remain more or less at the same level, or spread and become a much bigger thing involving all furred objects. We may, for the moment, call the factors we have pointed out in the above instances of learning: Readiness, Exercise, and Effect. By readiness, we mean, of course, either a native drive such as hunger, which gives rise to the random behavior we have described out of which the correct adjustive response is finally selected; or by readiness, we may mean as broad a thing as interest, purpose, or plan, something that is not as native and fundamental as a drive, but which can, as we have indicated above, be traced back through many experiences to an actual drive. In short, a drive is either immediately and directly involved, or else indirectly involved through mechanisms and previous learnings which have now become (Woodworth) drives in their own rights. What we call the "wish" for prestige, power, what we call the "spirit of competition" and the like, are all ultimately related to fundamental drives and the whole principle of pleasure and pain.

The person who most thoroughly and consistently has developed the laws of learning under the above general terms, is Thorndike. Working with animals, and with human beings, he stated these three principles which we can rephrase, for our purposes, in a somewhat broader form. By readiness, we shall mean, not merely any positive desire on the part of the organism which may take the form of a simple drive as we have shown, or a mechanism and interest which has developed out of such a simple drive, but also a drive or desire or interest, not positive and acquisitive, but negative and withdrawing. To be sure, by withdrawing from a painful stimulus or an unpleasant situation, there is implicit a desire for another state of affairs. Some learning may actually take

place under complex conditions of pain and avoidance, as when a child learns a multiplication table or some dates, not because he is directly interested in the table and dates, but because he wishes to avoid a foreseen and previously experienced punishment.

An animal may also learn to run a maze in the complex terms of a desire for food plus a painful stimulation when wrong turns and trials are made. But, in every case, it is clear that whatever the environment offers in the way of pain or pleasure, these things are ultimately in some sense, aspects of the total environmental situation. Probably much learning, particularly in sophisticated and intelligent people who have gone through much previous learning, involves this kind of mixed readiness. The poet or inventor, for example, may forego much immediate pleasure for the sake of an anticipated larger gain represented in his organism by earlier-instilled patterns that we call ambition or the desire for fame. Probably only the simplest behavior is uncomplicated by such considerations, and often there can be such static ambivalence that little or no learning will result at all, other than the continuance and intensification of the static condition itself.

As regards the middle term, exercise or practice, this also varies from instance to instance of learning. One may learn a new but simple mechanical puzzle with but little practice. One will learn an intricate act such as throwing three or four balls in the air and catching them, only with much practice. Also it is clear that practice may often be related, however obscurely, to other learning acquired at some previous time, though this statement must be taken with certain qualifications that we shall present later. Transfer of training, which would be involved here, is not the simple "disciplining" of the mind which some people take it to be, but rather involves a complex situation with common elements in the new act and the old one.

The question of satisfaction has been perhaps more argued than either of the others. Why, for example, out of many and varied incorrect acts performed in the trial-and-error period of practice, does the one correct or approximately correct act become singled out for permanent use? As a matter of fact, we really practice or repeat the wrong act or acts a score or a hundred times, but we do not really learn the act

until we perform correctly. We have, so to speak, in the intermediate stages, temporarily learned wrong acts, but with such wrong acts, if we are learning under capable tutelage or with adequate standards in mind, dissatisfaction, irritation, and the like are involved. When the cat we mentioned above inadvertently or by chance pulls the string that releases it, satisfaction is associated with that act. It has not, however, on the first such success, really learned the act; further repetition and further success are necessary.

What then happens to make it more likely that the successful act will finally be fixed in the nervous system? That is, what is the organic or neural correlate of satisfaction? We can only assume, though it seems reasonable in terms of our knowledge of the nervous system, that any circuit that is, at any instant, actually operating, remains open from receptor to effector for a brief period of time immediately subsequent to the action of that circuit. To put it another way, the plug is not pulled from the switchboard the moment a connection is made. This circuit, then, being briefly still open, the stimuli of eating and the attendant organic satisfaction will go out through this still open circuit and intensify it.

We see this principle clearly illustrated in the learning, by a rat, of a maze, or in the reciting of a poem by a child. The rat seems to become definitely oriented with reference to the last turn which immediately precedes the satisfaction of finding his food or his mate. Having learned that last turn, however, it has become so fixed through exercise and effect that it literally becomes a habit. His next problem is then the turn preceding the last, and so on backward, allowing, of course, for individual variations in different rats under different circumstances. He may sometimes stamp in two turns at a time. The child, too, may have to be prompted all through the early part of a poem he is endeavoring to recite, and then literally gallop through the last line or so which brings either the positive reward or praise or the negative reward that he is through with an unpleasant task. We see it, too, in adults who have learned a long poem; for some time there will be points in the recitation beyond which they cannot seem to go. So clear is this in experimental work that it has become something of an adage in memorizing, that it is best not to use all the time

available in one period but to divide up the time, so that we may find out where the weak connections are and strengthen them with a sort of subsidiary satisfaction.

Our remarks on the fact that the last-used circuit preceding satisfaction, positive or negative, actually intensifies that last circuit leads us directly into a consideration of the other kinds of learning we have mentioned, such as a child acquiring through one instance of experience a fear of a rabbit. Here the name of Pavlov, the Russian physiologist, comes to mind. The best statement for our purposes of the general meaning of Pavlov's experiments is as follows: if any given circuit involving an afferent sensory path, a connector path, and a motor efferent path, is active and open and functioning, then any other afferent sensory impulse occurring at the same or at very nearly the same time will tend to go out the same motor path that was already open and functioning. This merely means that any number of entering stimuli can, conceivably, depending on the conditions of the organism and the environment at the moment, go out a common path. Much of our learning, as we have said, is of this kind. The sight or the sound or the touch of a given furry object can all result either in the word "cat" or in an inner reaction of fear.

Reverting to the example given above of the boy and his breakfast and the rabbit, the situation is a little more complex, but it is to be understood in terms of these general principles. Thus, the sudden and unexpected appearance of the rabbit in his breakfast dish gives rise, because of his unpreparedness and the overloading of his circuits already working, to an inner reaction-pattern of fear, thus adding to the response-circuit. The sight and the sound and the touch of the rabbit occurring simultaneously likewise go out this inner efferent reaction-pattern of fear. Thus, a conditioned response is formed by one occurrence. Only in a verbal or common-sense interpretation did the rabbit cause the fear. The rabbit was merely a particular instance of a sudden and unexpected and overbearing stimulus causing the inner and additional response of fear. The rabbit was a mere happening in the environment; it might have been a cat or a football or a wet towel. It was the organism that formed the circuit under the given conditions. But other things being equal, the child will thereafter

react with fear to the sight or the sound or the touch of a rabbit, or if additional conditioning takes place, to the mere word "rabbit." In fact, it is perfectly possible to set up motor and emotional paths of discharge that are set off merely by words even though no concrete experience of the thing which the word stands for has ever occurred. Many people who react emotionally to the word "snake" have never actually experienced any concrete situation or stimuli involving snakes.

Many common fears and superstitions are simply conditioned responses to mere words. "Ghost," "communist," "nazi," "hell," "wrong," "bad," "nasty," are words to which we learn reactions through devious and complex conditioning-situations, for which there has been no actual but only a substitute basis in experience, though pleasure and pain, satisfaction and dissatisfaction, have been involved, as well as, often, long practice. Such conditionings or such instances of learning and modification may last a long time or, through further experience and learning, be modified and changed. The dog who drools at the sound of a bell will not continue to thus drool indefinitely unless some actual satisfaction in the form of food is given. Such a simple conditioning will just die out, but it is easily re-established by further instances similar to the original. In the case of the boy who is frightened by the rabbit or the adult who reacts with fear to mere words, it is not always easy to show what satisfaction or dissatisfaction is involved. But careful analysis of such cases shows that the motor and emotional reactions of fear do involve some sense of security or withdrawal which is satisfactory. The boy who is afraid of the dark, while not directly satisfying a drive in the primitive sense, is nonetheless avoiding dangers and pains which, though imaginary in reality, are still psychologically real.

This leads us to the question of certain criticisms of the whole readiness-exercise-effect theory as here presented. Tolman, for example, has made a criticism of this readiness-exercise-effect theory on the basis of certain experiments involving pain, a point we have already, in part, anticipated. First of all, it is clear that we do not always avoid pain, though common sense and everyday observation clearly show it is often a deterrent. The old adage that the burned child dreads the fire is true enough, but James

once remarked that if one knew that a severe pain in an eyeball meant the recovery of lost sight, that pain would be welcome and even sought out. We must also remember that many pains are only a partial aspect of a situation. We do a job we know we must do, even though we are tired and have a headache, because through previous learning and conditioning we realize that the ultimate end is worth achieving in spite of the present pain, and will bring ultimately a satisfaction and reward which will quite eclipse that pain. It would seem that the experiments which Tolman and others set up, involved just this complexity and hierarchy of pleasures and pains, and really go to prove Thorndike's laws when the whole, and not merely a part, of the situation is taken into account. For, in his experiments, even though the right steps were accompanied by pain, nonetheless there was a more powerful pleasure element involved, namely, the satisfaction of learning in spite of difficulties and deterrents. We have already remarked, and here emphatically repeat, that as the young animal, human or otherwise, grows older and more experienced, and has a greater and greater background of previous learning in the form of memory patterns, every stimulus is very complex and made up of many competing, divergent but nonetheless integrated elements. And likewise with responses. One may persevere through many years of adversity, pain, and suffering because of a fancied reward so utterly satisfactory in the mere contemplation that it takes precedence over all the deterrents. One will go through fire to save cherished possessions or dear friends. One will suffer the fears and privations of war because of the sense of satisfaction in serving one's country.

Another criticism of Thorndike's and Pavlov's eminently simple generalizations is that of the group of Gestaltists. The Gestalt school is loosely critical of the mechanical aspect of the interaction of the organism and the environment to such a degree that it almost seems, at times, that they deny determinism and the concrete relationships of the structure and function of the organism in relation to the environment, and seem to imply a sort of vitalism or mysticism. They seem to take the position that the real interacting factors are the forces resident in the body and in the environment so that the orderliness and integration of the or-

ganism and the environment appear to them to be a function of these forces, rather than the learning and modification of the organism in terms of the diversities of the stimulating environment. This may be merely a matter of language, and it is perhaps true that the Gestaltists add something to our understanding of learning in that they stress the complexities of action and reaction. But in this stress they seem often to deny or misinterpret the easily observed facts. They stress the interplay of forces, rather than the constantly changing action and reaction of receptors, connectors, and effectors in terms of these forces. They also seem to assume at times an inner predisposition to accept and react to a given stimulus or situation rather than analyzing the process whereby a situation through long trial and error has come to have a certain response. Take, for example, the word "COP." This, to an English-speaking person, is a gestalt or pattern to which he will react, in part, with a verbal-motor response, based on much experience and learning, as "policeman." To a Russian, however, with a different set of experiences and learnings, the response will be pronounced "sor," meaning "dirt" or "litter." It is a gestalt or pattern, to be sure, in each language, but it is nothing inherent and unlearned but is, on the contrary, the result of much learning. In short, depending on previous experience, we can learn wholes or parts.

Again, a child ultimately learns, as a result of much experience, that a triangle has three sides, a square four, and that a given rhythm is two-four or three-four. In other words, abstractions, forms, and relationships are as much a matter of learning as any simple concrete response. The appreciation of and reaction to form does summarize and integrate a large amount of experience, but such ability is the result of all underlying, previously learned concrete stimulus-response situations and is in no sense *a priori*. Köhler's apes quite evidently learned through experience both to join sticks together, which they had not learned previously, or to pile boxes upon one another, which they had not done before, but to call such things "insight" or the sudden formation of a gestalt, is merely to give them a new name and add nothing to their understanding. Without some previous experience of sticks and boxes they would not have had the insight nor would they have learned to solve their problem.

This brings us again to the question of higher integration in learning. We have already said that many entering, afferent impulses can and do, under the proper conditions, find a common exit. This is due to the very nature of the nervous system as well as to the chances of the environment. When Newton drew the conclusion from a falling apple that gravity held the solar system together it was, in one sense of the word, insight. But it should be noted that there were common elements involved in the circuits in question, such as the roundness of all the objects involved, plus the fact that the apple approached the earth. Newton had, to be sure, a sensitive nervous system, and much learning and experience of intricate and related cogency, and it just happened at that moment that they were grouped under a common heading and found expression in a common response. We may call this "thinking," but it is also learning. So we may say that the ability to draw certain far-reaching conclusions, in any abstract field of thinking or learning, is a very complex function of much related previous learning and the stimulating situation at the moment.

It should be clear that thinking is itself a trial and error performance, a special instance of adjustment or learning, in which there is not necessarily so much direct motor manipulation as in the instance of the golfer or the cat in the box, but rather a sort of indirect manipulation, through substitute stimuli and responses, such as words. We could not, for example, solve a problem involving a choice that will have future consequences merely by immediate, present, motor manipulation. Let us suppose that we have to decide where to go for a vacation a year from now and that we have two or three competing plans. We cannot, like the cat, concretely push and pull here and there or, like the rat, physically, at the moment, try this turn and that, but rather, we have to use counters and words in the effort to solve the problem. There is a drive present; there is a future satisfaction aimed at, but we have no guarantee it will ultimately arrive, and we cannot know, as in case of immediate mechanical situations, that we are right. Here the satisfaction is verbal and logical, but it is still satisfaction, in some sense, to solve some problems even thus. Whether we were right or wrong we shall have learned something, made further changes in the nervous

system and integrated ourselves better or not so well to the total complex environment. At least, an annoying state of affairs will be dissipated, verbally.

This leads us to a consideration of so-called purposive or teleological theories of learning in which again it seems as if a certain mysticism is present. What is called purpose is really, biologically and neurologically, a present set to solve a situation in the future. It is clearly impossible for a purpose to be other than a present and momentary set and integration of the organism, which fundamentally means, when we trace it back, either a drive, or a mechanism so strongly entrenched that, in Woodworth's phrase, it has itself become a drive. My purpose or intent to buy or prepare a meal is clearly merely the realization that I am hungry and am going to do something about it. The purpose has no mystic subsistence or existence apart from the make-up of the organism, and apart from such drive or mechanism. It is merely a matter of the awareness of a situation and the awareness of what to do about it, which are themselves matters of learning. And it is perfectly clear that in such situations many unforeseen factors may deflect the organism from satisfaction so that more learning will have to be acquired.

Take, for example, the question of learning to hit a bull's eye. The desire is there as a result of many complex former experiences, and the desire may in this case properly be called a purpose, but mere desire or mere purpose is not enough. We intend or purpose to hit the bull's eye with the first bullet we fire, but through neglect of such factors as lighting, the wind, our tendency to twitch, we do not hit it. The expert marksman is one whose learning is more commensurate with his intent or purpose, and even he may be thrown off in his achievement by new and hitherto unexperienced factors so that he will have to learn and integrate still further. All such efforts to ignore the simple and demonstrable facts of learning simply confuse the fundamental issue, namely, that there is an organism in an environment, and that it is the conditions of the organism and the environment respectively which bring about whatever result does occur. In short, we cannot escape the fact that the animal, human or otherwise, because of its very organic nature will strive to escape pain and to achieve satisfaction

in terms, at each stage, of previous modifications and learning.

Certain other subsidiary matters remain to be briefly discussed, namely, imitation, the ideomotor theory, and the question of "discipline" of the mind. As Thorndike properly remarks the child does not, in learning to write, imitate the writing of the teacher, because if the child had the ability to write as the teacher writes, it would not be imitation except in so loose a sense that there would be no significance in the term. What really happens is that the child, provided the desire or intent is present either to achieve success or avoid punishment, is simply stimulated by the agile and capable performance of the teacher. He then goes through a trial-and-error process in which, let us suppose, he is more and more successful so that his writing comes to resemble, more and more closely, the supposedly ideal specimen on the blackboard. But this is learning. If he is successful and gets praise he goes on with more learning; if he is punished and humiliated he may never learn. Readiness, exercise, and effect are always clearly present. One cannot imitate an expert in anything; one can only learn to approach a goal if there is interest, if there is practice, if there is satisfaction, and if it is within the possibilities of the individual to approximate more and more closely to the standard. To be sure, if I raise my right hand, almost anyone who has a right hand can do the same thing, but this is not learning through imitation, but reacting to a stimulus in terms of similar pre-learned abilities.

The ideomotor theory is another instance of misconception. If I tell someone to raise his right hand my words may, to be sure, cause such an act, but only if previous experience and learning have joined such a verbal stimulus to such a motor response. Were I to say it in a foreign language, unknown to the person to whom I give the command, no such response would follow. Words lead to motor reactions only when previous experience and conditioning have established such circuits. To tell Johnny, in words, to be "good," can only lead to such responses as have previously been joined to such a stimulus. To tell a person to be "calm," does not result in his being calm by any magic of the words. To tell a nervous person, "Don't be nervous," cannot have the intended or desired effect on his behavior, unless that phrase, by

long learning, is a touch-off signal for circuits and conditionings which will then function. In short, there is no necessary relationship between words and action but only a specific relationship as a result of previous experience and learning. One may indeed have a very extensive and delicate verbal knowledge of a given field even to the extent of being able to pass severe examinations therein, and yet be unable to perform other than verbally in that field. A verbal expert on how to run an automobile is not, therefore, a good driver, and contrariwise, the real motor expert who responds to cues and stimuli that are not verbal, may not be able to put into words what it is all about. A good painter may be a poor critic.

The question of "discipline" of the mind, like that of the ideomotor theory, has plagued the whole world of directed learning or education, for long long periods of time. The learning of Latin, for example, and the achievement of expertness in the field requires an arduous and long-continuous period of learning, and the formation of many and interrelated bonds, circuits, and connections. Let us suppose one has become a scholar in the field of Latin, and that one's accuracy of judgment, delicacy of perception, is vast. It should be clear that this accuracy and delicacy are a function of the many specific bonds and connections involved. One cannot just transfer this accuracy and delicacy to another field. It is quite broadly and popularly so conceived. An eminent physicist is often, alas, given credit for profundity because of his work in physics, when he writes a book on politics or religion. But his opinion and judgment in politics or religion will depend, in the main, on his experiences and learning and connections in these specific fields.

One can look at this problem from another point of view. The excellence in the field of physics is due to certain mechanisms, habits of thought and procedure in a given field of knowledge. The same techniques and mechanisms can, to be sure, be used in more than one field. The habit, for example, of examining premises, the habit of carefully gathering data, of testing each step in a procedure, would apply to many fields from chess to chemistry. So that one could readily say that a person of careful habit of thought and procedure could easily learn to become a master of another field if he used the same procedures in that field. But he

would still have to learn and become intimately familiar with the detailed data and relationships in the new field. But this is not what is usually meant by "disciplining" the mind or transfer of training. In short, we must say again, wherever one wishes to learn, one must have the desire or incentive, go through the necessary period of practice, and achieve sufficient satisfaction to stamp in the bonds and circuits.

This, then, is the story of learning or the inter-active modification of organism and environment. We have, to be sure, omitted the details of experiment, the niceties of criticism, and taken for granted some characteristics of the nervous system for which immediate and direct proof is at present lacking. But, by and large, both theory and practice agree in this: that we learn because we have an inner need to do so, that we have opportunity to bring it about, and that we find it worth while and satisfying. Without a drive or motive, fundamental or later acquired, without the final satisfaction of better adjustment, positive or negative, and without the intermediate trial and error process, we should be, not growing, adjusting, learning organisms, but mere passive objects completely under the control of the environment.

DANIEL BELL LEARY,
University of Buffalo

LEARNING CURVES, COMPUTATIONS IN COMBINING.—The purpose of this article is to describe for the student computations involved in various methods of combining individual learning records. The methods are described briefly for purposes of reference. They have been described, compared and evaluated by Hilgard (1938) and there does not seem to be a need for simply repeating his material here.

Learning scores cannot be simply added together because different individuals take different numbers of trials to reach whatever criterion may be used; nor can the experimenter use the same number of trials for each subject because different subjects would, in any given number of trials, have progressed to different points on their way towards mastery. The first solution for this difficulty was offered by Vincent (1912) who divided each record into tenths and then combined scores for the first

tenth, etc. If the number of trials in a record is an even multiple of ten there is no difficulty in deciding on the individual's score for each tenth. With other numbers of trials the question arises as to the correct procedure. Vincent simply took trials over the highest multiple of ten and increased the number of trials per tenth by one for enough tenths to take care of the extra trials, starting with the first tenth. For instance, a record with 32 trials would have 4 trials in the first tenth, the next four trials would be called the second tenth, and each of the succeeding tenths would contain three trials. Later modifications have interpolated on the theory that the amount learned per trial was evenly distributed over the trial.

Hunter (1917, 1934) was the first to use fractions of trials. If a record contains 32 trials he takes 3 trials and .2 of the next trial for the first tenth of the learning. He adds together the number of errors contained in 3.2 trials and uses this score as a measure of the amount of learning done during the first tenth. The second tenth contains the number of errors made during the next 3.2 trials. Loucks (1931) divides the number of errors in the tenth by the number of trials in that tenth, giving the number of errors per trial for each tenth. Hilgard and Campbell (1937) divide the number of errors per tenth by the total number of errors in the record and multiply by 100, giving the per cent of the errors made during the tenth. These procedures can be used with successes or with units of time as well as with errors.

Instead of calculating the score made during a tenth of the learning Kjerstad (1919) used the score reached at the end of each successive tenth. A graph is made for each record, using the abscissa for units of practice and the ordinate for units of learning, and the abscissa is divided into tenths. Each subject's score at the first tenth is read from the graph, these first-tenth scores are averaged, and the resultant is used for the location of the composite's first-tenth point. The next point on the composite graph is the average of the points reached by the end of the second tenth of the learning of the individuals. Where the Hunter procedures give a simple frequency graph the Kjerstad procedure gives an accumulated frequency graph.

In making Kjerstad graphs of individual records one may use any convenient interval and

after drawing the curve divide the abscissa into the number of fractions desired (ten in the examples used in this paper, but any number can be used). Instead of using convenient intervals on the abscissa it is desirable to stretch the graph to fit the whole length of whatever abscissa axis the paper provides. The abscissa is then divided up and the scores read off as above. This has the advantage of making the graph as long as the paper will allow and, of course, greater length permits more accurate reading. On the same grounds the ordinate units should be as large as possible.

Melton has prepared tables to simplify the graphing, assuming the use of an abscissa axis with 200 divisions, usually 200 mm. For each possible number of trials a table gives the number of divisions to be used for each successive trial in order to end exactly at the end of the paper.

Hunter-Vincent curves and their modifications use arithmetic in calculating their various points, but it seems usual to calculate Kjerstad-Vincent values graphically. These latter can also be done arithmetically and some workers may think that the arithmetic method is cheaper in terms of time and paper, and perhaps more accurate.

It is usual to assume with the Kjerstad procedure that the number of syllables correctly recited on one trial is the number learned by the end of the previous trial; so we may renumbers of correct anticipations in learning to the material is Trial No. 0, the next, the first chance to recite, is Trial No. 1, etc. Divide the total number of trials required for learning by the number of divisions desired. Multiply the quotients by the numerators of the respective successive fractions. Each of the resulting products will indicate (to the left of the decimal point) the number of trials and (to the right of the decimal point) the part of the gain on the next trial which will give the desired value.

The details of the procedure may be clarified by an example. A subject makes the following numbers of correct anticipations in learning 10 items: 0, 2, 5, 3, 6, 7, 5, 7, 8, 6, 9, 9, 8, 10. There are 14 trials including the criterial trial. Any learning which may have taken place during the last trial is not measured. The subject learned in 13 trials. Renumbering, Trial No. 1 would be that on which the score was 2; Trial

No. 2 would be that on which the score was 5; etc. If the record is to be divided into tenths each tenth will include 1.3 trials.¹ The score at the end of the first tenth will be the score at the end of Trial No. 1 (which was 2) plus .3 of the gain from Trial No. 1 to Trial No. 2. The gain is 3 and .3 of this is .9; adding, we have 2.9 for the score at the end of the first tenth of the learning. Similarly, the scores at the ends of the successive tenths are (repeating the one just found) 2.9, 3.8, 5.7, 6.6, 6.0, 7.8, 6.3, 9.0, 8.3, 10. If the example is worked out graphically it will be found that the values are the same. A graph made from these values will start at the first tenth of the learning. Zero can be used as a starting point for the graph on the theory that the subject knew none of these items before the learning started, which will give a curve containing ten parts instead of the nine we would get with the ten values given above.

The example given is in terms of successes, but exactly the same thing can be done with errors or with time units, except that the point from which the first tenth of the curve starts cannot, of course, be zero. We can assume, however, that the first score of the original record (before renumbering) represents the performance with no learning, and use it for a starting point. This is not done by Hunter (1934), Loucks (1931), nor Hilgard and Campbell (1937), although Hilgard recommends it (1938, p. 294).

Bills (1934, 196-7) has suggested a method of adapting the Kjerstad procedure to error scores. Actually, his suggestion does not do this. Instead of using his first score as a starting point he uses it as a measure of learning. The sample graphs he gives are presented as dividing the learning into fifths. However, he has added an imaginary trial at the beginning of each record and taken a fifth of the actual number of trials plus one. Hilgard (1938, 285) gives an illustration of Bills' procedure, and apparently

¹ It will be found convenient to prepare a card for each possible number of trials to learn, giving the number of trials to be included in each successive fraction. If there are to be ten divisions the card can be made easily from a multiplication table which goes up to 100×100 , simply starting with, e.g., 32, when there are that many trials in the learning, copying down the numbers under that multiplicand, and inserting a decimal point in each.

repeats the addition of the imaginary trial at the start, but since he discards the final trial this does not change the number of trials included in each fraction of the learning.

If Kjerstad's graphic method is to be applied to error scores it is essential that the first trial be considered as a base line instead of a measure of learning, and that the first criterial trial be included as the final point on the curve. If it is objected that this latter trial is subject to a special limitation in that by definition it must be higher than the just-preceding trial, we cannot discard the trial, we must discard the section of the curve which includes it.² Melton has pointed out that this limitation produces an artifactual end-spurt in the curve of successes (1936). The end-spurt can be avoided when the shape of the latter part of the curve is important by his procedure of counting trials required to reach a given fraction of the criterion instead of counting scores reached at the ends of given fractions of the trials required to reach the criterion, but this introduces a starting-spurt, and it gives a curve which must always go up and can never go down.

It has been said that it is probably undesirable to have part of a trial making up a complete fraction of the learning; so one should have more trials in each record than divisions of the records. Care should be taken not to cover up significant features of the learning (such as plateaus, for example) by combining records. For discussion of both these points the reader is referred to Hilgard's 1938 article.

LIE DETECTION — ITS BODILY BASIS AND TEST PROCEDURES.—It is elementary but important to remind the reader at the beginning that "deception," hereafter discussed, is assumed to be a *conscious* act. Errors of fact or understanding, pathological lapses of memory or responses resulting in deception but with abnormal motivation like those of the psychopathic liar, form no part of our present detection problem. For the purpose of this discussion a "lie" may be defined as a mental, verbal, or bodily response of *conscious* deception.

I. CRITERIA OF DECEPTION

1. *Commonly Observed Behavior.* This consists of bodily movements or verbal responses which may be observed without the aid of instruments or scientific apparatus and which may be voluntarily controlled and altered by the deceiver. No two sets of voluntary responses during deception are precisely similar. Whether or not this voluntary behavior is symptomatic of deception or of some other type of response can only be *guessed* by the observer.

Two general groups of behavior symptoms are commonly considered to be symptomatic of deception: fear reactions and dominant defensive responses. Voluntary fear behavior is generally assumed to include the following reactions: running away; looking guilty, confused, panic-stricken; making inconsistent statements; delaying or hesitating in answering questions. Subjects who react thus are partially defeated by the stimulus situation and in consequence they behave less efficiently.

² Hilgard (1938) calls attention to the fact that if the criterion contains more than one trial, the trial preceding the criterion also has a special limitation in that it must be below the level of the succeeding trial, whereas the second trial preceding the first criterial trial may be at the criterial level. The trial preceding the first criterial trial may go down, but cannot go up.

This type of behavior has been used since the earliest records of man as ipso facto evidence of guilt. Such reactions are admissible in court as evidence in determining whether or not a defendant, accused person, or cross-examined witness is guilty of criminal or deceptive conduct. In some cases, no doubt, an assumption of guilt may be justified. In other cases, however, such weak and fugitive reactions do not evidence guilt. These behavior symptoms ipso facto are evidence of fear only, and fear is aroused to greater or less degree in every person who knows he is suspected of crime or deception, whether he is guilty or innocent.

A second type of behavior commonly observed is the dominantly defensive pattern of reaction. A murderer may face his accusers boldly. He may manufacture a clever alibi for himself, furnish false clues, or destroy clues which point to his own guilt. He may manage to appear innocent in face and manner. He may elect to run away; but if he does so, his flight will be well planned and cleverly executed. Subjects in this group master the stimulus situation and act dominantly to divert suspicion or conviction of guilt from themselves.

2. *Scientific Criteria of Deception.* By means of scientific instruments and laboratory procedure, *involuntary* movements of a subject's body may be detected and recorded. Such behavior cannot be controlled by the would-be deceiver. Involuntary responses symptomatic of deception may be mental reactions or changes in bodily or physiological activities such as breathing, heart beat, glandular secretion, or other visceral changes. In general, these internal bodily responses are mediated by the autonomic or "sympathetic" nervous system which is not under voluntary control. In using such involuntary responses to detect lies, two problems are encountered. First, the discovery of reactions which invariably accompany deception; and secondly, the correct interpretation of the total pattern of involuntary responses recorded in light of the stimuli which evoked them. Provided these two problems are solved, involuntary bodily responses may be expected to furnish scientifically reliable criteria of deception.

II. PROCEDURES FOR DETECTING DECEPTION

1. *Legal and Police Methods.* First we find police, detectives, lawyers, judges, juries, and other crime investigators observing the behavior

of suspects for the purpose of discovering reactions of the fear type which may be accepted as guilt.

Second, various tortures, called the "third degree," are used to force a suspect to confess to a crime or deception with which he is charged. The errors in both these methods are obvious. Neither evidence of fear behavior nor pain-impelled confession offers reliable proof of guilt. Decisions by a jury unaided by scientific criteria of deception proved to be less than 50 per cent correct during Marston's early experiments in the detection of deception in the Harvard Psychological Laboratory (*Systolic Blood Pressure Symptoms of Deception*; J. of Experimental Psy. 1917, Vol. II, p. 112).

2. *Scientific Procedures.* With one exception, all scientific procedures reported to the literature have attempted to detect bodily symptoms of emotional disturbances caused by or accompanying deception. Six thousand years before the birth of science as we know it today, the Chinese used a rice-chewing test to determine the truth or falsity of an accused person's testimony. The subject was required to chew rice for a certain length of time and was then told to swallow it. If he could do so, he was assumed to be innocent. If he could not, he was adjudged guilty. The reaction which these primitive investigators were unknowingly testing was the effect of fear upon the secretion of the salivary glands. If a suspect could swallow rice, it meant that the saliva was flowing freely into his mouth. If he could not swallow it, it meant that his fear was inhibiting the salivary secretion. The test actually consisted of observing in a crude way a glandular reaction symptomatic of fear. But the Chinese, in all probability, had no idea that they were dealing with any such reactions. Consciously, they were only trying to discover some unknown variety of emotion caused by lying.

Lombroso suggested that the measurement of blood volume and pulse by a plethysmograph type of apparatus might detect guilt in criminals, stating that he had tried this in one criminal case.

Binet, using similar apparatus, noted similar effects produced by emotions accompanying suspense and tension in a subject who had before him an unopened letter containing news of the expected birth of his child.

Cellini mentioned in his autobiography that

his father noticed a marked effect on his pulse, while the child was ill, at the mention of Benvenuto's musical performances.

These observations are historically interesting insofar as they suggest the possible influence of general emotional tensions upon blood circulation phenomena, but in actual fact they seem to have had no bearing whatever upon subsequent researches seeking to discover identifiable deceptive emotional reactions.

During the nineteenth century specific scientific tests for various emotional excitements caused by varied stimuli, including those of deception, were attempted in psychological and physiological laboratories. The psycho-galvanic reaction, as measured by the galvanometer, was found to be symptomatic of almost every type of emotional reaction. This test apparently measures changes in the amount of sweat secretion in a skin area through which a low voltage electric current is passed. Movement of the big toe, involuntary gripping of the hand and salivary secretion measured by scientific techniques were similarly investigated and found to be, in varying degrees, reliably correlated with general emotional disturbance.

In the late 1890's the first scientific test for fear type reactions caused by deception was developed simultaneously in widely separated psychological laboratories by Jung and Wertheimer. This became known as the association reaction-time test. It consisted of reading to the subject a list of words some of which related to the crime or subject of deception and some of which did not. The subject was instructed to reply to each word with the first associated word which occurred to his mind. The time elapsing between the experimenter's pronouncement of a stimulus word and the subject's response was recorded by a stop watch or chronoscope in fractions of a second (tenths to thousandths, depending on the apparatus used). The theory of the test was this. If the stimulus word aroused fear in the subject's mind because it was related in some way to the crime or guilty act which he was attempting to conceal, his reaction would be delayed. Therefore, if a subject's reactions to crucial words were significantly slower on the average than were his reactions to irrelevant words, he would be adjudged guilty of attempted deception. This clearly was an attempted scientific test of the fear type of behavior above discussed.

Later tests of the same type proposed by psychological investigators were a shifty-eye test and the involuntary movement test. The first, devised by Dr. Henry T. Moore at Dartmouth, consisted of recording a subject's eye movements while being questioned. If he turned his eyes away from the examiner during crucial questions, he was assumed to be deceiving.

The first tests of emotions accompanying *dominant* defense behavior during deception were the respiration and blood pressure tests. Vittorio Benussi, working at the University of Graz, reported that respiration varied in a significant manner under influence of deception. The ratio of inspiration divided by expiration, he said, was greater *after* lying than before; but was greater *before* truth telling than after. He also stated that a clever or successful liar showed more pronounced variations of the type described than did a weak, fearful, and unsuccessful liar. Benussi's procedure, therefore, was designed to test *dominant* defense behavior.

In 1915 Marston, working in the Harvard Psychological Laboratory, reported that systolic blood pressure increased significantly during deception, the increase being greater with efficient liars than with ineffective deceivers. In 107 cases judged simultaneously by the blood pressure test and a jury, the test failed four times while the juries failed fifty-four times. Marston held that the blood pressure symptoms of deception constituted a test of dominant emotion accompanying the extra effort necessary to deceive with consequent release of additional nervous energy. Marston also reported as a result of research on some two hundred laboratory subjects that the systolic blood pressure curve symptomatic of deception rises in a characteristic form to a peak near the point of greatest effort and most intense dominant emotion motivating the deceptive act. This phenomenon has been called by later investigators the "peak of tension."

At the beginning of this section on scientific procedures an exception was noted to the psychological type of research in deception. Dr. R. E. House, a Texas obstetrician, attempted to compel suspects to tell the truth by injecting scopolamin. This type of procedure is a scientific extension of police methods designed to break down a subject's resistance and compel

confession. House himself, reporting his results in 1922, called his method "A Truth Serum Third Degree." House gave three injections of scopolamin and two hours later questioned the subject. He admitted that "you can obtain the same effect—with chloroform, gas or ether, but scopolamin is preferable because its effects wear off more slowly than any other anesthetic." That loquacity can be caused by drugs or alcohol has never been disputed. But psychologists generally agree with Larson that "under the influence of an anesthetic or sedative—a patient may talk freely with a resultant mixture of truth and falsehood." In a scopolamin test conducted by Larson in San Quentin prison, a convict "confessed" that the examiner was implicated in his crime. It seems obvious that the truth or falsity of drugged responses still remain to be detected by some different type of procedure. Moreover, even if proven true, confessions thus obtained are not admissible in court because the subject is not in a normal mental condition while confessing.

3. *Laboratory Examination of Scientific Procedures.* Critical investigations of the most promising scientific test procedures have been made as follows. Prior to 1920 the psychogalvanic reflex as a criterion of deception had been tested by a number of investigators and discarded because of its oversensitivity and difficulties of technique. But in 1936 Father Walter E. Summers, S.J., Ph.D., reported successful experimental results with this test in the Fordham University psychological laboratory, using a modernized apparatus for recording psychogalvanic reflexes. The principle of the test remained unchanged. Dr. Summers' procedure was to ask the same crucial question twice, recording the psycho-galvanometric variations accompanying the subject's responses. If the subject were lying, the galvanometric reaction was said to be greater the second time than the first; whereas if he told the truth, the second reaction was smaller than the first. Using this criterion in laboratory experiments with artificially devised deceptive situations, Summers reported 98 to 100 per cent reliable detection of deception.¹

Other investigators have failed to verify the

high reliability of this test. Inbau writes: "In detection of deception cases of an experimental type (i.e., card tests, etc.) such responses afford very reliable criteria of deception. But in actual cases—the electrodermal responses have not been found to be of much practical value as deception criteria."

The psycho-galvanic reflex is an extremely sensitive indicator of undifferentiated emotional response but has not been found to respond specifically or in any characteristic way to the deception stimulus situation.

The word association reaction-time test proposed by Jung and Walthimer was investigated in more than twenty psychological laboratories throughout the United States; also in several laboratories in Germany, France, and Italy. Besides the experiments with this test reported in the literature, there probably were many hundreds of unrecorded class-room experiments in American colleges. Review of all available reports of these widely scattered experiments shows that the association test failed to indicate deception in approximately 25 per cent of the cases where deception was present. In 1913 Marston conducted experiments at Harvard for the purpose of discovering the cause of this 25 per cent failure. Using a more carefully controlled laboratory technique than is possible in applied tests, he found that approximately 25 per cent of his subjects responded more quickly to the crucial or deception stimulus words than they did to the irrelevant or control words. Marston concluded that one person in four lies faster than he tells the truth. Slow liars are delayed by fear and mental confusion; i.e., they are partially defeated by the stimulus situation. Rapidly responding liars react dominantly, conquering the situation and releasing additional nervous energy to meet the menace of detection.

Benussi's proposed respiration test was investigated by Dr. Harold E. Burr, who devised an improved technique for determining the inspiration-expiration ratio. Burr concluded that Benussi's criterion, if practically obtainable, promised considerable reliability in detecting deception. But he further concluded that this respiratory test was of less diagnostic value than the blood pressure technique.

Marston's proposed systolic blood pressure test for deception has been investigated by a considerable number of research psychologists

¹ *Science Can Get Confession*, by Rev. Walter G. Summers, S.J., Ph.D.; *Fordham Law Rev.*, Vol. VIII, No. 3, 334.

and physiologists. Most of these researchers used some modification of the original apparatus, making simultaneous blood pressure and respiratory records. Marston's first research included a determination of blood pressure by the intermittent method using a Tyco's sphygmomanometer and also a series of recordings of circulatory phenomena—blood pressure, pulse rate, and blood volume by the continuous method using an instrument of the Erlanger type which recorded its variations on a smoked kymograph drum. In his published reports, however, Marston mentioned only the Tyco's technique, which he believed more effective, taking four or five readings of the subject's systolic blood pressure to the minute and noting them in figures on paper.

Dr. John A. Larson, working in the police laboratory at Berkeley, California, repeated Marston's experiments, using the continuous blood pressure method with an Erlanger sphygmomanometer. He reported that a comparison of the two methods showed the continuous recording to be more reliable because it largely eliminated the individual error of the operator when taking blood pressure. Since this method gave no quantitative determination of the blood pressure level at any time, Larson took the blood pressure with a Tyco's at the beginning and end of his test and also at other intervals. Larson also combined with the blood record a respiration record taken simultaneously by means of the usual pneumograph tube and recording kymograph drum. This also had been done originally by Marston and by Marston, Burt, and Troland during their war investigation of lie detector tests for the National Research Council. Larson, however, placed more stress on the breathing symptoms of deception and the correlation of respiratory irregularities with variations in the blood pressure. He agreed essentially with Marston as to the reliability of the blood pressure test for deception if properly administered under controlled conditions by an experienced operator with suitable scientific training, and Larson made notable contributions to test technique and apparatus. Using standard laboratory equipment in his initial researches, he later constructed a combined blood pressure and respiration recording instrument of polygraph type easily carried by hand to the scene of criminal investigation. This instrument, or similar ap-

paratus, has since been employed by most of the operators using the lie detection test.

Leonard Keeler, who received his first training in this field from Larson, made an assemblage of blood-pressure and respiration-recording apparatus similar to Larson's, and after a great deal of applied work with the test directed the manufacture of this assemblage of apparatus in convenient form for police use and other applications of the test under the name of "Keeler Polygraph." Some seventy of these instruments are now in use by law enforcement officers throughout the country. Keeler later added a recording psycho-galvanometer attachment to this instrument; though he agrees with other investigators that the galvanometer criteria are less reliable than blood pressure (checked by respiration) in diagnosing deception.

With regard to the interpretation of blood pressure symptoms, many investigators content themselves with a somewhat vague description of the emotions accompanying deception. These they describe as "emotional tensions" or "emotional disturbances." Some operators conclude that blood pressure variations are caused by "fear," or "fear of detection," though fear has been shown conclusively to result in a *drop* of blood pressure level. Marston, who proposed a theory of psycho-neurologically described primary emotions (dominance, compliance, submission and inducement) maintains that the only reliable blood pressure criteria of deception are those which reveal the aggressive emotions of *dominance* and *inducement* accompanying the attempt to deceive. It is his contention that errors in the interpretation of test records result in good part from confusion between fear type response symptoms, which may be caused by any number of irrelevant factors in the total stimulus situation, and the dominantly defensive behavior criteria above cited which can be definitely related to the deception attempt itself.

III. PRACTICAL APPLICATIONS OF TEST PROCEDURES

1. *Respiration Test.* So far as can be ascertained, the respiration test for deception has never been applied in actual practice except as a supplement to the blood-pressure technique.

2. *The Word Association Reaction-Time Test.* The word association-reaction time test was applied originally by Jung in several private cases. Its use in the United States has been limited almost entirely to laboratory experiments and class-room demonstrations. Though private investigators have informed the writer that this test is occasionally useful in criminal cases, no records are available.

3. *Psycho-galvanic Test.* The psycho-galvanic test was applied by Father Summers in two New York criminal cases where test results were offered as evidence in court. In *People vs. Kenny* (167 misc. 51, 3 N. Y. Supp. 2nd 348 (1938)) the trial court admitted Summers' results obtained by testing the defendant with a galvanometer which he called a "Pathometer." Over the prosecutor's objection, the jury was permitted to consider the deception expert's opinion as to the defendant's innocence or guilt. Dr. Summers testified that the "Pathometer" was "effectively 100 per cent efficient." In a subsequent case, however, *People vs. Forte* (167 Misc. 868, 4 N. Y. Supp. 2nd 913; 279 N. Y. 204, 18 NE 2nd 31 (1938)) where Dr. Summers again attempted to introduce psycho-galvanometer test results in evidence, the trial court ruled against him and the New York Court of Appeals sustained the lower court's ruling. It should be noted that this decision does not exclude the blood pressure-breathing test in New York, since the latter test was not offered in evidence.

Father Summers' applied as well as his laboratory researches have been continued by Dr. Joseph K. Kubis, Associate Prof. Psy., Grad. School, Fordham University. Kubis states that he has been consulted by city and state police authorities; by the Armed Forces on problems concerning deception detection; has instructed the Director of the Scientific Laboratories (N. Y. State) in the use of his method; and that the White Plains, N. Y., D. A.'s office has used it with success (*Electronic Detection of Deception*, Electronics, 1945, Apr., 192.); also on medical patients to test whether they did or did not believe their delusional states (*Psychogalvanometric Investigations in Psychoses*, by Kubis and associates, *Psychosomatic Medicine*, VI, No. 3, 237).

Aside from Summers and Kubis' work, it would seem that the galvanometer has been used by practical investigators largely as an

adjunct of the polygraph type apparatus, testing blood pressure and respiration.

4. *Blood-Pressure Test.* The blood-pressure test for deception, with or without the breathing test, has been applied to a very considerable number of uses.

In 1917 Marston, Troland, and Burtt examined defendants in twenty cases in the Boston Municipal Criminal Court, using primarily the systolic blood pressure test, supplemented by respiration, reaction-time and galvanometer tests. So far as findings could be verified, all judgments of truth or deception based upon blood pressure criteria were correct. The investigators concluded: (1) that the blood pressure test has demonstrable practical value in determining truth or deception of a witness' story; (2) that confessions occur under conditions of this test which it had been previously impossible to extract; and (3) that by detecting guilty emotions accompanying hitherto unsuspected portions of a witness' testimony, new and fruitful channels of police investigation are opened.

These conclusions were later supported and verified by the findings of all subsequent workers in the applied field.

In 1918 Marston administered blood pressure tests to 70 messengers at Surgeon General's Headquarters, Washington, D. C., for the purpose of discovering the thief of important missing objects. All subjects were negroes of emotional temperament and blood pressure variations in all tests were great. But the thief was successfully detected.

Also in 1918 Marston, then a Lieutenant in the Army, taught blood pressure test technique to fourteen soldier operators, all with previous legal and psychological training. The operators tested suspects who had opportunity to steal articles from the barracks and made 74.3 per cent correct judgments. The b. p. test records were then turned over to Marston who made 97.1 per cent correct judgments. Marston concluded that the blood pressure test is reliable only if judgments are made by a thoroughly qualified operator with sufficient training and experience.

In 1922 W. M. Marston, LL.B., Ph.D., administered the blood-pressure test to James A. Frye, a negro accused of first degree murder in Washington, D. C. Marston tested Frye in the prison hospital while waiting trial. The test showed that Frye was innocent. At Frye's trial, defense

attorneys offered Marston as an expert in lie detection to give his opinion as to the truth of Frye's testimony based on test results. Chief Justice McCoy of the District Supreme Court excluded the proffered testimony on the ground that the test, to be admissible, should have been made in Court while the defendant testified. "If so offered," the Judge said, "this test might be admitted in evidence." Following this court's dictum, the blood pressure test was administered in 1924 to defendants accused of assault and battery in Indianapolis City Court by Edward F. New, an attorney associated with Marston in blood pressure test work. Test results were admitted in evidence and the findings of the court were in accord with the results of the tests. This was the first time a deception test had ever been admitted as evidence by any court in America.

Meanwhile, in 1921, John A. Larson, Ph.D., M.D., had begun to apply the blood pressure test in police investigations at Berkeley, California. Larson was extraordinarily well qualified for this work by training and experience—he received practical police training under Chief Vollmer at Berkeley, and during his university studies specialized in physiology, endocrinology, and later in psychiatry. Dr. Larson first applied the blood pressure-breathing test in a case of suspected thievery in a girls' dormitory at the University of California. Ninety girls were tested and the thief was discovered. While in California Larson tested 861 persons in 328 criminal cases, many of them cases of murder and other major crimes. As a result of test procedure, 182 suspects confessed, leading Larson and police associates to advocate substitution of the deception test for the "third degree." Three hundred and ten persons were cleared of suspicion by the test. Larson's results, so far as could be checked by evidence and court findings, showed a high percentage of reliability. A supplementary report on 193 subsequent cases at Berkeley, 1934-1936, not yet published, shows that Larson's tests produced confessions in 66 cases out of 92 judged guilty. Hundreds more criminal cases were later tested successfully by Larson while Assistant State Criminologist in Illinois. Prisoners were tested at the State Penitentiary and State Reformatory and suspects examined in connection with police and prosecuting attorneys' investigations. Still later Larson tested many cases as a psychi-

atrist in Recorder's Court, Detroit, with effective findings. Larson's pioneer work proved the practicability of applying scientifically administered deception tests successfully to criminal investigations.

Leonarde Keeler, A.B., LL.D., studied deception test technique under Larson and Vollmer at Berkeley, California, in 1921. In 1923 Keeler applied the blood pressure-breathing test to cases in the Los Angeles Police Department, using apparatus of polygraph type similar to Larson's, which Keeler constructed. Later, as a member of the Illinois State Criminologist's Staff, and as Professor at Northwestern University, in charge of the Scientific Crime Detection Laboratory, Chicago, Keeler used the test in a large number of criminal investigations in various states of the Middle West. He and his assistants also have tested thousands of personnel cases for banks and commercial employers. Keeler's testimony and the b. p.-breathing test records upon which it was based were admitted in evidence by stipulation between prosecution and defense counsel in the Wisconsin case of State vs. Laniello and Gugnano (see *Journ. Crim. Law and Criminology*, Vol. 26, No. 2, July, 1935). Findings of the jury were in accord with Keeler's test judgments and all jurors reported to the Judge that the tests were of considerable help in determining the credibility of defendants and of witnesses who contradicted the defendants' testimony. This is the first instance of admission of test results in evidence where the test itself was made outside court, a psychologically preferable procedure to that required by Judge McCoy's dictum and followed in cases above discussed. Keeler, now in private practice in Chicago, has tested numerous cases for the Army and Navy during World War II, and at its conclusion screened 270 prisoners of war chosen to be trained as police officers and returned to Germany to assist United States occupational forces.

George W. Haney, formerly associated with Larson and now a personnel consultant in Chicago has used the b. p.-breathing test, which he refers to as the Polygraph detection of deception technique, in servicing many businesses where honesty of employees is an important factor. His clients include banks, currency exchanges, mercantile houses, transportation (bus) companies, trucking companies, vending machine companies, warehouses, and armored car

services. Actual statements of employees, according to Haney, show that 40 to 60 per cent of them working with money or merchandise steal sometime during the course of their employment. Haney also states that 97 per cent of people on the street have taken something of value during their lifetimes.

From 1925 to date Marston, a consulting psychologist, has applied the blood pressure-breathing test technique to several hundred cases of marital adjustment, divorce, personality analysis, family conflicts, social and pre-marital adjustments; and such problems as applications for pardon, surety company investigations and lawyers' investigations of clients and witnesses. Associated with Marston in test work are E. H. Marston (lawyer, psychologist); O. B. Richard (psychologist); and C. D. King (psychologist).

Applied test work has been done by the following who originally worked with Larson:

Canty (psychologist, Ass't Director Psychopathic Clinic, Detroit Recorder's Court; Instructor Police Science, Wayne Univ.);
 Broom (lawyer and former head of Detroit Police Training School);
 Lyon (Juvenile Court psychologist, lecturer Criminology, Univ. of Illinois Medical School);
 C. D. Lee (Berkeley Police Department Captain, manufacturer of "Psychograph" instrument similar to Larson's and Marston's apparatus);
 O. W. Wilson (Prof. Police Science, Univ. of California);
 Greening (former Chief Police, Berkeley, Calif.);
 Waterbury and J. Wilson (former Police Inspectors, Berkeley, Calif.);
 Bledsoe (Berkeley Police Technician);
 Leonard (Prof. Police Science, Pullman State College, Wash.);
 Gabrielson (Chief Police, Honolulu);
 Elliot Ness (former Commissioner Pub. Safety, Cleveland, Ohio);
 Dean (formerly Berkeley Police Dept., now Brig. Gen. U.S.A.);

Also by men associated with Keeler: Inbau (lawyer), Mulbar (Michigan State police), Jaycox (Wichita, Kansas, Chief of Police), Trouvillo (Chicago City Police), Funk (Penna. State Police), Wm. D. Jack, M.D. (medical consultant), and Smith, Schrieber and Beecher (examiners).

And, carrying on Father Summers' work: Joseph F. Kubis, Ph.D. (Fordham University). Many other able workers have applied and are applying this test effectively in the various fields whose pioneers are discussed above.

IV. STATUS AND EVALUATION OF TEST PROCEDURES

The association reaction-time test for deception, proved unreliable by laboratory research, is not in practical use.

Psycho-galvanometer records are taken by some operators in conjunction with the blood pressure and respiration tests.

Scientific opinion among psychologists with regard to the dependability of the blood pressure-breathing test for deception was at first divided. In 1926 a questionnaire prepared by Charles T. McCormick was sent to 88 members of the American Psy. Ass'n. Thirty-eight replies were received from psychologists whose work concerned this field. Eighteen believed the deception test was sufficiently accurate to warrant consideration by judges; 13 were of contrary opinion; and 7 gave answers of doubtful classification. (See 15 Calif. Law Review 484).

During the twenty years of lie-detection test development and application which have followed McCormick's survey, psychological opinion has swung more definitely toward the conclusion that this procedure is sufficiently reliable for practical use in criminal and personnel investigations and probably in court if the tests are made under proper conditions and results are used with sufficient safeguards. Among 55 opinions of psychologists obtained recently by the writer, 42 approve applied use of the test with proper safeguards; 5 believe the test is not yet dependable; and 8 endorse use of the

test for certain specified purposes and not for others.

The legal status of the test differs in different jurisdictions. In the *Frye Case*, above cited, lie-detection test evidence was excluded by the trial court and this decision was upheld by the appellate court (*Frye vs. U. S.*—293 Feb. 1013). But this was in 1923 and the Court's dicta suggested that the b. p. test might become admissible if made in court and if and when it gained sufficient "scientific recognition among physiological and psychological authorities." Whether this time has yet arrived could only be determined by bringing another test case in the District of Columbia Courts. In 1933 the Supreme Court of Wisconsin sustained a trial court's refusal to permit a defendant charged with robbery to take a deception test and put the results in evidence (*State vs. Bohner*, 210 Wis. 65). This court also remarked that the polygraph test "may ultimately be of great value in the administration of justice," but "a too hasty acceptance of it during this stage of its development may bring complications and abuses." Since a Wisconsin trial court subsequently (1935) admitted polygraph test evidence, in *State vs. Loniello and Grignano* above cited, it would appear that the Bohner case decision, while denying the right of a criminal defendant to demand admission of deception test evidence if the trial court chooses to reject it, does not bind the courts of Wisconsin to reject such evidence when offered by stipulation of both parties. Rejection or acceptance of the test, therefore, would appear to depend, in Wisconsin, upon the form in which such evidence is offered and upon the discretion of the trial court.

In several other states where the test has been accepted in evidence by lower courts, the law would seem similar to that of Wisconsin. No appeals from trial court decisions admitting the test in these states have so far been recorded.

B. p.-breathing test evidence has been admitted in trial courts in Indiana, Illinois, Ohio, Michigan and Wisconsin; possibly also in other states according to cases reported in newspapers but not otherwise verified. So far as ascertainable, no Appellate Court decision at the present time rules out b. p.-breathing test evidence if offered in a form approved by the trial court. On the other hand, courts everywhere are inclined to be extremely cautious about admitting

this type of evidence for two reasons: first, competent test operators themselves emphasize the fact that there is a margin of possible error in test judgments; second, because it is feared that general acceptance of deception-test evidence in court may open the door both to insufficiently qualified test operators and also to fraudulent and dishonest persons ready to fake any findings for which they are paid. The writer agrees with the general attitude of American courts requiring every precaution in admitting deception-test evidence to guard against these two causes of possible injustice.

With regard to the margin of error which may be expected in the results of tests made by expert operators, the opinions of examiners differ. Larson, whose own results have proved remarkably accurate and reliable, states that the test if given by inadequately trained operators without the aid of supplementary data furnished by medical and psychiatric examinations may show an error as great as 50 per cent. "Neither medical nor criminological training alone is sufficient," says Larson, "but a staff consisting of the investigators, the examiner ideally with psychological training, and a psychologist and licensed physician or a forensic psychiatrist. The last three named should be present throughout every examination. Conducted by a suitably trained staff—deception tests may be invaluable in service, first in the primary investigation as an adjunct to the present methods of cross-examination, and, secondly, in court clinics and private laboratories as a part of psychiatric technique."

Keeler states: "In personnel cases for banks and department stores, the results of which are of immense importance to the business, approximately 80 per cent of those giving test results indicating deception have made confessions later verified, or have otherwise been definitely proved guilty. In criminal cases approximately 62 per cent of those giving test results indicating guilt have made verified confessions or otherwise been proved guilty. In approximately 10 per cent of the cases the test results are of such nature that no definite diagnosis can be made. In slightly over one per cent of the cases, the wrong diagnosis has been made."

Inbau writes: "... there is a margin of probable error of approximately 10 per cent. There is also an additional group of cases, approximately 20 per cent, in which test rec-

ords are too indefinite in their indications to permit diagnosis."

Marston agrees with Larson that inadequately trained operators may show a high margin of error in judging test results. He agrees also with the authorities quoted that from 10 to 20 per cent of all records made may furnish inadequate data for reliable judgments of truth or deception. This, however, should not be regarded statistically as a failure or inadequacy of the test, since further records can easily be made and always are made by expert and competent operators. This correction applies also to the margin of error to be expected in all records made even by expert operators—the records can be and should be verified by additional tests whenever the slightest obscurity appears in the results obtained. Keeler advocates making two records of every person tested and reports that the second record shows greater symptoms of deception than the first if the subject is attempting to deceive. If all the precautions above discussed are taken by an expert and adequately trained operator, Marston finds that the margin of probable error is considerably less than 10 per cent; in his own cases, so far as results can be verified, the error is approximately 5 per cent. This applies to all types of b. p.-breathing test applications above described which seems to make the tests, in the writer's judgment, sufficiently reliable for practical use, including use in court when employed with sufficient legal precautions and psychological controls.

There is one aspect of the reliability of deception test results which has been ignored by the courts and seldom considered by deception test proponents; namely, the comparison between the accuracy of deception test findings and the findings of fact by the average jury. Marston made a study of juries' reliability in Washington, D. C. (Journ. of Crim. Law and Criminology, Vol. XV, No. 1, May, 1924) and found that the average completeness of six juries' findings of fact was 35.9 per cent while the accuracy of conclusions drawn from this small percentage of facts was approximately 59 per cent for a male jury and 71.4 per cent for a female jury based on witnesses' testimony during direct examination. On cross-examination testimony the female jury's accuracy was 71 per cent and the male jury's accuracy 68 per cent. Combining the scores of accuracy and

completeness, the findings of the average jury could be rated no higher than 52 per cent reliable. Subsequent analysis of juries' findings, so far as they could be checked in the cases of 4,800 prisoners in the Texas Penitentiary and 438 other cases in various parts of the country studied by Marston, indicated that juries' unaided judgments of the truth or deception of testimony can be valued at little better than 50 per cent. Many defendants are convicted because they try futilely to conceal private affairs of no importance to the question of their guilt or innocence. The jury, with no adequate criterion by which to form a judgment on the important portions of defendant's testimony, frequently considers his story entirely false because of an irrelevant deception. The result in such cases is a wrongful conviction based upon the jury's unaided judgment of the veracity of testimony. Comparison of the reliability of the truth or deception of testimony with the reliability of blood pressure-breathing test results obtained by a properly qualified expert shows a 30 to 40 per cent greater reliability of test judgments. Perfect justice can never be attained by any human procedure; but there seems little doubt that a much higher degree of justice already has been achieved in many hundreds of cases by b. p.-breathing test technique than would otherwise have been possible.

LOBOTOMY.—The operation of bilateral prefrontal lobotomy, to give it its full name, should be of very special interest to psychologists for three reasons. They are naturally interested in mental hygiene, and this development promises much in the way of relief of psychotic symptoms. Secondly the post-operational changes that take place in mentality may throw much needed light on the localization of brain functions and other theories of neural activity. In the third place, psychologists have a

direct professional interest in the matter. Their cooperation with the neuropsychiatrist and neurosurgeon is usually sought and appreciated, since it has been proved that they can assist materially, not only in the selection of cases but also in the prediction of the mental consequences and in determining the surgical adequacy of the operation. Thus the status of the psychologist *vis-a-vis* the psychiatrist will be measurably improved, a result professionally very desirable from the standpoint of both professions.

Prefrontal lobotomy consists in cutting an estimated 80 to 85 per cent of the subcortical connections of the frontal areas with the rest of the central nervous system, leaving the overlying cortex practically intact. Specifically, the neural pathways that are chiefly disrupted are those running between the thalamus and the frontal lobes, in other terms the thalamo-frontal radiation. The cells of the cortex anterior to the incision suffer little or no deterioration, but those of the nucleus medialis dorsalis of the thalamus show severe retrogression.

The operation was first performed in 1935 by Egas Moniz, a Portuguese neurosurgeon, for the relief of psychotic symptoms in certain types of mental patients. By means of a specially devised instrument operating through a trephine hole in the upper temporal region, Moniz cut spherical cores in the white matter, leaving them in position to be absorbed or encysted. When this operation was ineffective, minute quantities of alcohol were injected at different depths between the cores forming a "prefrontal barrier." Patients suffering from agitated depressions were most affected by this "psychosurgery," schizophrenics less so. Out of 20 cases, 7 recovered and 7 were improved.

The operation was introduced to America in 1936 by Freeman and Watts, (3) but they soon discarded the Moniz technique for deep, straight line incisions along the plane of the coronal suture, taking care to stop short of the cortical layer of grey matter. By a series of radial cuts, they endeavored to sever as much of the subcortical connections as possible. If the arc of the fan shaped incision is not deep enough or if the plane of the cut is too anterior, mental changes are not apparent. If the cut is too deep or too posterior, the results may be too severe, the patient relapsing into a somewhat vegetative existence.

To ensure the surgical adequacy of the procedure, Freeman and Watts perform the operation under a local anesthetic and test its effects at the time by questioning the patient or getting him to count backwards, add, or recite the Lord's Prayer, etc. When the fourth and last quadrant is severed, disorientation, mental confusion, and relief from anxiety are at once apparent. However, this is imposing a very severe proof of the surgical adequacy of the operation. The psychologist's cooperation can, we believe, obviate the use of local anaesthesia, with the resultant strain on the patient's fortitude.

For a few days following the operation there are decided changes in behavior. For the first day or two there is mental confusion, so that Freeman and Watts remark: "This disorientation is so characteristic that it is used as a yard stick for satisfactory operation. While it does not always occur on the operating table, if it is not present on the first post-operative day, it is likely that the operation will be a failure and that the preoperative symptoms will return within a short time." (4) Peterson (9) however does not agree that mental confusion has this prognostic significance. Other typical reactions are incontinence, increased appetite, loss of initiative, regression to childish behavior, physical inertia, somnolence, and psychomotor retardation. In a few days these symptoms tend to disappear. For successful cases the depression and physical agitation are relaxed and general improvement follows, extending over a period as long as a year or more.

It is not within the province of this article to give anything more than the barest statistical summary of the results in terms of percentages cured or improved. A considerable literature is springing up on the subject reporting the types of cases operated upon and the observed effects. Besides Freeman and Watts, the most prolific contributors, Lyerly (7) reports work done at the Florida State Hospital. He states that 74 per cent of his 55 cases were moderately or greatly improved to the extent that they could leave the State Hospital, have returned to work or become socially adjusted. In 1943, out of 136 patients operated on between 1936 and 1942, Watts and Freeman reported good results in 98 cases or 72 per cent, and fair results in another 23 cases or 17 per cent. Thus some improvement was noted in 89 per cent of cases. (5)

These results are more favorable than those presented in other studies. Typical of these is Kisker's report on 20 cases operated on in Columbus State Hospital, Ohio. Six improved to the point of being released, while 4 others made a more satisfactory hospital adjustment, 7 remained unimproved, and 3 died. (6) Thus improvement resulted in 50 per cent of cases, causing Kisker to remark: "Considering the extremely poor prognosis of the cases selected for operation, this figure is all the more remarkable." His cases are comparable with those operated on by Dr. Ralph Cloward at Kahohe Hospital, in Hawaii, and reported upon by Porteus and Kepner (12). They found that 11 out of 20 patients or 55 per cent showed some improvement. This group, too, included a proportion of cases with extremely unfavorable prognoses. Latterly, with a better system of selecting patients, the proportion of successes has increased materially. Incidentally the "batting average" of the psychologists in predicting correctly the outcome of the psychosurgery is about 85 to 90 per cent. Petersen and Buchstein (10) observed decided improvement in 16 of their 29 cases and a lesser degree of success in another 11 cases.

Schrader and Robinson (13) have reported results on one of the largest groups of lobotomy cases (207), with good results in 52 per cent of cases, fair improvement in another 19 per cent. They summarize results of 13 studies involving 601 patients. Of these, 47 per cent improved markedly and 24 per cent made moderate progress. The mortality was 5 per cent. Undoubtedly careful selection of cases will improve the record of successes very materially.

On the basis of this now extensive experience, the consensus of opinion seems to lean heavily in favor of this new surgical procedure, though caution is recommended by most investigators. The cases most suitable for operation seem to be those suffering from obsessive tension states. Some patients exhibiting chronic agitated depression have made most remarkable recoveries. One of the most striking of these that came within the writer's observation was that of a woman 64 years of age who had spent 27 years in mental hospitals and was, prior to operation, so cantankerous or depressed as to be unapproachable. Now, two years subsequent to lobotomy, she has developed into an easily manage-

able, intelligent and interesting old lady, somewhat crotchety at times but on the whole sane and reasonable. Some cases, chiefly schizophrenics, show disappointing effects, while in others the changes seem most remarkable and even miraculous.

We come now to the extremely interesting question of the neurological basis of the mental changes and more specifically the light thrown on the functions of the prefrontal areas of the frontal lobes. Moniz held the theory that the operation benefitted the patient by freeing his personality from such dominating ideas as chronic anxiety, delusions of persecution, hypochondriacal or grandiose ideas. Neurologically speaking, he held that the fixed synaptic patterns that mediate personality are disrupted and new circuits of response are set up of a more satisfactory social nature. This viewpoint seems to find support as regards emotional components from Kisker, who says that "one basic factor in postlobotomy personality status is the recanalization of emotional energy. . . . The disorganization occasioned by the destruction of the anterior thalamic radiation permits new lines of identification which, when properly canalized, result in a personality more highly integrated with the world of object reality."

The theory of recanalization agrees with hypotheses put forth at various times by the writer. These may be very briefly stated.

All responses are circular and to some degree repetitive. A simple example is provided by Allport (1) of an infant saying the syllable "Da." The auditory pathways are stimulated and the excitation radiates to the centers for speech, which under the principle of neurobitaxis are placed in close conjunction. Thus a neural circuit is completed which later becomes part of a wider circuit which involves conscious imitation of a similar sound repeated by the mother, and still later is associated with a still wider neural circuit involving the image of the father, with whom the sound is associated. The writer has insisted that all purposeful responses have this characteristic of circularity. (11)

Those stimuli to which it is advantageous for the organism to respond are termed relevant, the most relevant being those that involve the widest neural circuits, or in other terms, the most massive response. Naturally, those that have an emotional reference are the most relevant since they involve the whole organism.

The mechanical principle in setting up a circuit of response is the contraction under stimulus of nerve cells which is communicated to nerve processes, bringing about synaptic contact in the same way as a tangled skein is tightened by tugging at the free ends.

Those stimuli for which there is already a prepared path are instinctive, and closed circuits are also characteristic of activities which have become automatic. In other situations where choice of reaction is possible, some arcs of the circuit are not complete, and in such problems of adaptation there must be a mental rehearsal of action, an anticipatory excitation of certain neural pathways, a mental trial and error solution.

Personality, in the writer's opinion, can best be defined, following G. W. Allport's summary (2) in terms of the individual's "unique adjustments to his environment," his characteristic style of response. In the abnormal personality certain situations acquire a mistaken relevancy; the responses may become either over-emotionalized or over-intellectualized. If the former, the behavior is excitable or compulsive; if the latter, it may be hesitant, confused, consciously ineffectual. In either case, there is no proper integration or balance between the functions of the frontal lobes and the thalamus. The only way to achieve a better balance is to break up the existing synaptic patterns so as to admit of the formation of new personality trends. This the operation of prefrontal lobotomy effects.

More specifically, what is affected is apparently the mental rehearsal or pre-rehearsal, the anticipatory excitation which seems to be mediated by the prefrontal areas. The evidence for this seems fairly conclusive and is based not only on the observed ward behavior of post-lobotomy patients but also on the results of tests of planning and foresight.

That planning is adversely affected by lobotomy seems to be a common observation of investigators of the problem. One of the latest contributions on the subject is Freeman and Watts' (5) "Behavior and the Frontal Lobes," which supplements the reports contained in their book on Psychosurgery (3) and brings their experience up to date. In the writer's opinion this latest statement of Freeman and Watts has a greatly improved cogency and definiteness.

Foresight, they say, is badly impaired for a

period after operation, particularly in the matter of personal and interpersonal adjustments. In everyday affairs, or in the pursuit of a profession, especially where there is no marked emotional component, decisions may be hasty but adequate. In more intimate personal matters the decisions are likely to be over-hasty and deficient in foresight. As regards new or original adjustments, patients are likely to fail. "Creative work of any considerable complexity is a closed book for most patients." In these authors' opinion lobotomy cases lack, not only foresight, but the mental energy to carry their efforts forward to the goal. The presumption is that the main spring of this energy comes from the thalamus. To use my own descriptive terms, I would say that the behavior, from being over-emotionalized, has become under-emotionalized. Freeman and Watts also emphasize their view that the frontal lobes "give the individual an image of himself as he is appearing from moment to moment." This inadequacy of personal reference I would express in another way by saying that the neural systemic circuits that underlie characteristic styles of response, or individually unique adjustments, having been disrupted, the patient has lost the rudder of consistency. He has no fixed conception as to how he should respond, no image of himself as he was. While the new personality is building it is not surprising that the patient relapses into childish attitudes. "There is something childlike in the directness and ingenuousness of people after lobotomy," say Freeman and Watts. Some of these viewpoints are confirmed by Kisker, who also emphasizes the emotional intellectual balance that is therapeutically affected by lobotomy. "Considering," he says, "the widely held view that the cortex maintains an inhibitory function over the activity of the diencephalon, it is of interest to note that lobotomy is not ordinarily accompanied by chaotic emotional release. Rather, there appears to be a redistribution of emphasis in the emotional sphere."

Schrader and Robinson have noted in respect to schizophrenic patients who have undergone lobotomy that the average case "learns rather slowly and has little initiative when alone." Nichols and Hunt's case also showed a deficit in initiative essential to planning as was shown by "failure to supply spontaneously fresh modes of attack on a problem apparently resulting from an inability to abstract that aspect of the

situation causing the difficulty." They also note that the patient "seems to have lost the capacity to sustain several parallel lines of activity separately." (8)

Among the patients reported on by Porteus and Kepner, lack of initiative was a marked feature of post-operative behavior. Though ward work made few calls for planning capacity or foresight, whenever these were observable they were defective. The essence of deficiency in initiative, it should be observed, is a failure in voluntary planning. Incidentally, one may remark that the old saying that "Satan finds some evil still for idle hands to do" loses its force in the case of the lobotomized patient. Lacking the drive which the thalamus contributes to intellectual activities, the patient is content to carry out merely familiar tasks. It is worth emphasizing that it is voluntary planning which is lacking and ability to attack effectively new problems. Those skills or activities which were familiar to the patient are retained, and under direction or the spur of necessity may be carried on without apparent loss of efficiency, but he will not of his own volition attack new problems. The effective planner must be fertile in expedients, and the lobotomized individual is remarkably infertile in working out alternative solutions.

It is, however, in the testing situation that the deficiency in planning is best demonstrated. Generally speaking, there is no consistent loss of ability of the kind that is examined on the Binet scale unless it be in those situations where mental flexibility is most in demand, such, for example, as the application or interpretation of proverbs. The patient frequently will give the literal meaning of the proverb without being able to apply it to other situations. It is, however, in the Maze Test where deficits are most apparent.

In many cases the planning capacity of psychotic patients is already impaired, so that the average Maze score is relatively low, that of 44 patients prior to lobotomy being only 11.15 years, or about 3 years below the adult average score. In the first place, it should be remembered that ordinarily a reapplication of the Maze tests within a six months' period would result in the raising of the score through practice effects. Probably 80 per cent of normal individuals with Maze scores less than a perfect performance on the first trial improve on a sec-

ond application. What happens to the lobotomy cases?

In spite of an inferior initial performance, thus leaving ample room for improvement, these 44 cases scored 9.3 years in their post-lobotomy average, or 1.85 years below their former average of 11.15 years. In terms of I.Q. points the deficit is over 13 points. Instead of 80 per cent improving their score, the situation is reversed. About 73 per cent had scores lower than their prelobotomy performance, 4 per cent were unchanged, and only 23 per cent improved. Two individuals who increased their scores on the second application were both reoperated on, and in each case the third application of the maze showed the characteristic decline. The average I.Q. gain of the 10 patients who improved their scores was only 7.7 points. The only patient with a relatively large increment of 28 points committed suicide, and the autopsy showed that the operation had been inadequate. The interesting paradox is that unless the maze score declines on the second application the operation is usually surgically insufficient to bring about any marked remission of the psychotic symptoms. As far as the Hawaii experience goes, an improvement in post-operative score, taken in conjunction with absence of remission of the psychotic behavior, seems to be an indication for reoperation.

The average loss for 32 patients whose Maze scores decline was 18.6 points, and this very marked deficit would seem to support the clinical observation that initiative and voluntary planning capacity are grossly impaired. Nevertheless the gains through psychosurgery clearly outweigh the losses, provided that a careful selection of patients for lobotomy is made.

Certain criteria of selection are in process of validation. One seems to point to the exclusion of patients exhibiting hebephrenic features in their behavior. Apparently the emotional regression has proceeded too far in these cases for operation to benefit. On the same principle those who show marked intellectual regression are also unsuitable. It is, however, sometimes very difficult for the psychologist to measure deterioration, as so frequently the behavior masks the real mental status. A third criterion is rather obvious. Those of initially low mental level cannot be expected to benefit except as regards institution adjustment. To what extent brain surgery should be employed for the pur-

pose of quieting the patient and making him easier to manage is an ethical problem which must be left to the psychiatrists to decide.

As regards type of patients, it has yet to be proved that the diagnostic label has very much value in selection of cases. The agitated depressions, provided that there has not been too much mental impairment, and the compulsive tension states are the conditions that seem to respond most favorably. Paranoid conditions, especially when the delusions have a sex basis or marked sexual components, are less likely to be relieved, while auditory hallucinations do not seem to be eliminated. Schrader, on the basis of his experience, would exclude schizophrenics unless they are of the catatonic type.

However, it should be emphasized that the operation is very new and the results are not yet either wholly accessible or assessable. Hence the selective criteria are merely tentative, and in the meantime even hunches are sometimes successful. What is badly needed is a psychological institute for research on the effects of lobotomy. Only in this way can we be assured of systematic follow-up activities for the assessment of what promises to be the most promising development in the field of neuropsychiatry which has yet appeared.

What would be the result if all mankind were to undergo prefrontal lobotomy? The writer has already suggested that the effect might well be to reduce humanity to a dull level of mediocrity. In a personal communication, Dr. Schrader has put forward the interesting theory that patients with a prefrontal barrier occasioned by operation have many points in common with primitive peoples. There is a great deal of weight in this suggestion. In ethnic groups where government by the tribal elders is the rule, individual voluntary or creative planning is at a minimum. There is very little initiative possible, since tribal custom regulates very strictly all activities. The individual who steps out of the rut of custom meets with social disapproval, which has exceptional weight in conditions where a sense of "belonging," or tribal fellowship, is most necessary to individual happiness. (The savage, incidentally, is the world's greatest "joiner," cannibals having instituted the first luncheon club.)

In primitive life there are, therefore, few opportunities for individual self-expression. Thus

initiative, voluntary planning, creative originality are deficient. Prehistoric man with highly developed frontal areas would have been like a car with a powerful engine and a weak steering mechanism. The emotional life of savages, which is the dynamics of behavior, is not less than ours, but the range of goals on which to expend itself is limited. It becomes concentrated on what we consider insignificant objects. The great gap between an uncivilized and a civilized mind is that neither can understand the other's enthusiasms.

There is no doubt that some people's planning capacity has run ahead of their judgment and vision so that their emotions have become involved in the pursuit of foolish goals. It is unfortunate that the neurosurgeons were not able to get hold of Hitler a dozen years ago. Lobotomy might have been the most effective cure for Nazism. Whether all the world would be happier for being "mediocritized" as well as "democratized" is, however, an open question. The surgeons, given their way, have now apparently the means of making mankind into an unoriginal, unworrying, inexcitable, untroublesome mass. If Atlantic Charters and all else fails to bring lasting peace, we might call in the neurosurgeons.

M

MATURITY, THE PSYCHOLOGY OF.

—Interest in the psychological aspects of aging goes back at least several thousand years; however, it is only within the last few decades that comparative studies of adult age groups have put such interest on a scientific basis. Young human adults have been exhaustively scrutinized since the very inception of psychological science, but older individuals have failed to arouse curiosity on an equal scale.

A few scattered papers on later maturity appeared during the first thirty years of the present century, and in 1923 G. Stanley Hall published a book on senescence which was intended as a companion volume to his earlier work on adolescence. The Stanford Later Maturity Research Project, conducted by Miles and his associates in the early thirties, was the first systematic attempt to investigate the subject. A number of important inquiries on old age have recently been reported by other workers and the volume of publication in this field is gaining rapidly, spurred on by an impending vast increase in the number of older persons. We are, therefore, in a position to sketch, in a preliminary sort of way, the psychology of maturity.

Although our knowledge of the adult years is still fragmentary and incomplete, the age trend with regard to most psychological traits and abilities seems unmistakable. In most functions, the course follows that of a parabolic curve, reaching a peak in early adulthood, with a slow decline through middle life, and a sharp drop during the senile stage. Changes are usually gradual and are often a long time in becoming manifest, in contrast to the rapid sequence of events during the developmental years.

Decline takes place early and with greatest certainty in those abilities which are based primarily upon bodily activities. Although many changes in psychological functioning have their source in the aging of the tissues, the relationship is not always of a one-to-one nature. This

may be attributed to the existence of compensatory mechanisms and physiological reserves.

The pattern of decline is not identical for all abilities or in all individuals and it is frequently the pattern rather than the specific losses which determines the extent of personal adjustment. Moreover, the social environment and the person's relationship to that environment decides whether a given deficiency is disabling or of little practical consequence.

A. SENSATION AND PERCEPTION

Decrement with age in such sensory functions as vision and audition is well established. Although there are significant individual differences in the rate of loss for each of these processes, the trend is the same for all persons. For example, Miles (1933) reports that none of the men in his 70-89 age group had visual acuity equal to that of the average of his 18-29 subjects.

Beyond the fourth decade there is a gradual reduction in visual acuity, a slowing of dark adaptation, a narrowing of the visual field, and a rising threshold for light stimulation. Decrease in the elasticity of the lens begins in childhood, and it is almost totally gone before the age of 60; impaired accommodation is associated with the loss in lens elasticity. The narrowing of the visual field has been attributed to nerve cell degeneration. The incidence of visual pathology increases with each succeeding decade.

Losses in hearing are gradual, appearing first with reference to the higher tones. In general, the higher the pitch of the tone, the more rapid is the loss. Stevens and Davis (1938) report very slight hearing losses for all ages up to 60 for sounds no higher than 512 cycles, and that hearing is within 10 decibels of normal for a pitch of 1024 cycles. However, at frequencies above 2000 the loss at advanced ages becomes very marked. Montgomery (1940) has found that at the higher frequencies the decline is less for women than for men, while

at the lower frequencies the decline is greater for women.

Summarizing the findings regarding hearing decline, Miles (1943) points out that at 8192 cycles the age curve from 20 to 60 years is parabolic, the median loss reaching 40 decibels. Decrement is evident at 1024 and 2048 cycles at age 40. At 50 there is slight impairment in the higher middle ranges, with a sharper loss evident at 60.

Other sense organs also undergo changes in middle and later maturity. Pearson (1928) has found an increasing number of people exhibiting absence of vibratory sensibility in each decade beyond the third. Critchley (1931) reports a decreased sensitivity to internal pains among older persons. A marked decline in the number of taste buds during the senescent period has been observed by Arcy (1935). Roughening of the skin contributes to decreased tactile sensitivity of the elderly. Presumably, changes take place in all of the sense organs of the body.

Sensation antedates perception and is essential to it. Accordingly, in view of the sensory changes which have been described, it is not surprising that perceptual processes are affected. Perception also depends upon cortical elements and these elements age along with other tissues. Experimental results indicate that both the speed and the span of perception are adversely influenced by the process of aging.

Typical of the findings on perception are the results reported by Price (1931). Using a Weaver tachistoscope, he examined subjects ranging in age from 6 to 89. He presented six varieties of material, allowing a standard exposure of 0.1 of a second; the materials used included short sentences, colors, letters, groups of lines, erroneously written common expressions, and numbers. Glasses were permitted. Score was determined by the number of items correctly perceived. There were small age differences in performance between 12 and 49, with decline becoming evident after the age of 30 and fairly marked after the age of 50. Individuals of 74 did about as well as children of 8 or 9.

B. MOTOR ABILITIES

Using a group ranging in age from 8 to 80, Miles (1931) studied the fate of such hand movements as reaching and grasping, digital

flexion and extension, and rotation of both dominant and subordinate hands. His results indicated rapid improvement in coordination ability from 8 to 18, followed by only a very gradual slowing down until about age 50, after which the decline was more pronounced, but still small. Individual differences were conspicuous at advanced ages.

Miles (1931) also investigated hand pursuit reaction accuracy and simple reaction speed by the hand and foot to an auditory stimulus. The digital and foot reactions remained fairly constant until the age of 50, after which decline began to appear. It appeared sooner in the foot reaction than in the digital one. Pursuit movement speed increased up to age 18, a plateau was maintained until about 30, beyond which the decline was fairly sharp.

Ability to keep a car on a straight course (eye-hand coordination) and speed in raising the foot from the gas pedal and depressing the brake have been studied by DeSilva (1936). Basing his conclusions on a sample of 2000 cases between 15 and 65 years of age, DeSilva found that reaction time reached a peak at 23, with a steady decline thereafter. The difference in reaction time between ages 23 and 65 was .06 seconds, which means that a car driven by the older man would travel an additional 5 feet before being halted, assuming its speed to be 50 miles per hour. Steering control reaches a peak at age 19, with a steady drop thereafter. In spite of the changes in eye-hand coordination and reaction time, the older driver is less likely to be involved in accidents than a driver of the youngest group, because he is more safety-minded, drives more slowly, less frequently and under less hazardous conditions.

Administering the Link McFarlane Cube Assembly Test, which measures intelligence, construction dexterity and perception, Miles (1935) found a gradual reduction in speed from the twenties to the sixties, with a more precipitous drop thereafter. He recruited as subjects a representative group of adults ranging in age from 20 to 90. Significantly, older men with mechanical experience achieved the young adult speed rate and were definitely superior, in the 50-69 age group, to men without mechanical training who had equal intelligence and formal schooling.

The McFarlane Coat Assembly Test has also been given by Miles (1935) to a representative

age sample with similar results in the matter of age-speed decrement. However, women did markedly better on the test than men, as evidenced by the fact that the average 70-year-old woman was better than the average 20-year-old man. Here again, experience plays a very important role in performance.

C. LEARNING AND MEMORY

Learning and memory are inseparable, being aspects of a common process. Although the products of learning may persist even after the ability to learn has been greatly impaired, learning must take place before memory is possible. On the other hand, the nature of a person's apperceptive mass is a factor in determining the ease with which he may assimilate new material.

Thorndike, Bregman, Tilton and Woodyard (1928) found only a slight drop in learning ability from a peak between 22 and 23 up to age 45, after which the rate of loss was more pronounced. Tasks which sample "basic modifiability," such as drawing lines of specified length while blindfolded, learning a letter code, associating numbers with nonsense syllables, and learning to write with the non-preferred hand, showed the largest amount of age-decrement. There was almost no loss in elementary-school subjects, and university work was mastered with approximately equal facility by both the younger and older age groups. On the basis of their findings, Thorndike and his associates estimate an overall deterioration of about 15 per cent in learning efficiency between the ages of 22 and 45. They also point out that losses in learning ability may be compensated for by more thorough methods of work and greater effort.

Evidence has been gathered by Sorenson (1933) which indicates that persons over 60 exhibit no reduction in their ability to comprehend the meaning of standard test paragraphs, when such persons are compared with younger ones of the same educational and occupational levels. As a matter of fact, the oldsters were even superior in vocabulary ability. Sorenson has also been able to show that lack of practice in learning is unfavorable to the retention of learning ability.

The status of motor and verbal learning at various ages has been investigated by Ruch (1934). One of the motor skills involved sim-

ple eye-hand coordination and the other was identical except that the subject observed his behavior by means of a mirror. The verbal tasks included the learning of false multiplications, a series of nonsense equations, and a series of logical associations. The subjects were divided into three age groups: 12-17, 34-59, and 60-82. The 60-82 group did more poorly on all tasks than the middle-aged group. Impairment was greatest in the acquisition of nonsense material and mirror learning and least for direct-vision learning and paired associates. Ruch concluded that learning loss is greatest where there is conflict with established habit patterns. The scores of the 34-59 group were superior on some tests to those made by the youngest group and inferior on others.

Memory is the keystone of most, if not all, of the higher mental processes. Changes in memory usually are accompanied by modifications in thinking, imagination, learning and other processes. From the standpoint of mental functioning, the amount of material lost is often subordinate in importance to the type of material lost. The degree of integration existing in the surviving material is also an important factor with regard to adjustment. Some of the methodological difficulties involved in the study of memory have been described recently by Jones and Kaplan (1945) in their appraisal of changes in senile psychotics.

Observation and recall as a function of age has been studied by Jones, Conrad and Horn (1928) with the aid of motion pictures. They constructed completion and multiple choice tests for three motion pictures, using a representative rural New England group. Marked decline began to appear about 45, with rectilinear decrease to the age of 60. At 55 the median had dropped to a level below that represented by the average 13-year-old.

Employing 11 different memory tests, Gilbert (1941) studied memory loss in a group ranging between 60 and 69 as compared with the performance of persons 20-29 years of age. The older group performed more poorly on all tests, the least discrepancy between the two groups being in visual memory span for digits and the greatest difference being in retention of a Turkish-English vocabulary list.

In summary, it should be emphasized that individual differences in learning and memory are marked at every age level. Moreover, the

pattern of change with regard to these functions is not identical for all persons; it has been demonstrated that persons with superior intelligence and education maintain their learning and memory abilities longer than others who have not been equally favored.

D. INTELLIGENCE

Intelligence, as it is defined in our various mental tests, is a composite made up of a number of special abilities. Tests differ in the emphasis placed upon speed versus power and in the relative weights assigned to such functions as vocabulary, arithmetical ability, memory, and general information. Accordingly, the results reported in the literature on the performance of adults vary with the test instrument used, the conditions under which it was administered and the type of subjects employed.

Mental capacity must be translated into ability by extensive training and constant repetition before it is measurable by our verbal intelligence tests; this must be given consideration in evaluating the scores of older persons not favored by education or occupation. An uneducated man of 60 or 70 may do poorly on a test in spite of high capacity and a desire to give a good account of himself. Until longitudinal studies giving attention to occupational and educational factors are undertaken, we shall not be in a position to assess accurately the intelligence of older persons.

Loss of ability does not always connote loss of capacity, although loss of capacity would be followed by loss of ability. Old people may have more ability along certain lines than young people of greater basic capacity.

Most studies have relied upon intelligence tests designed for children or young adults and the validity of their use with older persons has been questioned by Lorge (1945) and others. It has been suggested that many test items which are passed by youngsters on the basis of thinking are solved by older adults on the basis of memory or by mental processes different from those employed by children. Moreover, the criteria which may be adequate for testing the mental ability of school children and young adults may not be fair standards for persons of advanced age who are far removed in time from their academic experiences and attitudes. Some have argued that the weights assigned to the different types of test items

should vary with the several age groups. The development of norms of test performance for the older age groups is a step in the right direction; this has been done for the Wechsler-Bellevue Intelligence Scale. However, the development of norms for adults does not dispose of the objections which have been raised with regard to test content.

Motivational factors have not always been comparable in the various published studies. In some instances, subjects were paid for their participation in the investigation. In others, they were tested on a voluntary, non-remunerative basis. In still others, the subjects were examined under conditions of maximum effort and with a goal of some kind clearly in view. A further difficulty arises from the fact that although an older person may be highly motivated, he is far removed in experience from the school situations which foster competition. The greater lability of the young may play an important role in their somewhat superior test performance, although it does not fully explain their higher average scores. Unfortunately, there are few published studies on the performance of older persons under conditions of intense motivation.

Accurate sampling of the older elements in our population is complicated by the reluctance of many aged persons to be tested. Jones and Conrad (1933) have shown that less competent persons in older age groups frequently attempt to evade examinations, thus raising the average scores. This has been confirmed by Thorndike and Gallup (1944) who used a vocabulary test of a steeply graded type in a national survey.

The three most widely publicized studies of mental ability during the period of maturity have been published by Miles and Miles (1932), Jones and Conrad (1933), and Wechsler (1943). All three studies are in substantial agreement in indicating rapid gains during adolescence, with a peak in the vicinity of 20 years, followed almost immediately by a gradual decline. Jones and Kaplan (1945) have drawn smoothed age curves based on the data of these three investigations, showing that Wechsler, and Miles and Miles found more rapid decline than Jones and Conrad.

Miles and Miles (1932) found that the correlation between score and age during the period 20-95 years is approximately $-.50 \pm$

.02 and the discrepancy between the mean scores in the third and ninth decades is 9.9 S.D. diff. Using a population of 2000 which she considered representative of various age periods and a short form of the Otis test, C. C. Miles (1935) found a decline in mental ability beginning in the twenties. The drop became fairly steep between 40 and 60, and very precipitous beyond 70. Describing data gathered in the standardization of the Wechsler-Bellevue Intelligence Scale, Wechsler (1943) reports finding that intellectual ability reaches a maximum between 20 and 25, and begins to drop immediately thereafter, although decline is not marked until much later. At age 60, mental ability stands at 75 per cent of the 25-year-old level.

Since intelligence is not a unitary function, it is not surprising to find that the items which make up our tests do not decline at the same rates. Investigators agree that vocabulary and general information hold up better with age than items based on memory ability or logical thinking.

Utilizing data gathered by Jones and Conrad (1933), Jones and Kaplan (1945) found greatest loss in the Army Alpha subtests dealing with analogies and directions, and the least loss in vocabulary and general information. Wechsler (1939), evaluating data based upon the Wechsler-Bellevue Adult Intelligence Scale, has found that tests which hold up with age include object-assembly, information, vocabulary and comprehension. Those particularly subject to decline are block-design, similarities, substitution, arithmetical reasoning, and digit span. Wechsler's findings indicate that age-decrements on performance tests are as large as those occurring with timed verbal tests. Miles and Miles (1932) found that loss was greatest in items dealing with arithmetical reasoning and number relations, and least on vocabulary and synonyms-antonyms. Miles (1943) reports that scores on an information test of intelligence (Terman-Miles) exhibited increment up to the late forties, with decrement after age 50.

As has already been stated, most workers agree that vocabulary holds up extremely well until, at least, the beginning of the senile period. Vocabulary studies, however, have been the objects of a number of criticisms, one being that the vocabulary lists employed are not truly

representative of the words at the command of older persons. For example, as individuals progress in certain professions, such as medicine, there is a tendency for their vocabularies to become specialized. Kaplan (1943) has demonstrated that even when vocabulary levels are maintained over considerable periods of time, the same words may not be passed on the first and second tests. Presumably, vocabulary should increase during the life span of an intelligent adult armed with a dictionary.

Babcock (1930) has developed a Test of Mental Efficiency in which she uses the score attained on the Terman vocabulary list as an indication of a person's early adult intelligence, and a series of learning and speed tests to measure present efficiency. The difference between the two scores yields a measure of deterioration. The Babcock test has been criticized on the ground that although the correlation between vocabulary and general intelligence is high, it is far from perfect. Furthermore, Shakow and Goldman (1938) have presented evidence showing that vocabulary levels may begin to drop in the sixties, making vocabulary an unreliable index of early mental level. In a later publication, Shakow, Dolkart and Goldman (1941) found that psychotics had poorer vocabularies than non-psychotics, and that senile demented, on the average, were more deficient than arteriosclerotics with psychosis.

It cannot be denied that speed of performance is markedly reduced in older persons and that tests which emphasize speed discriminate against the more advanced groups. Still, speed is important in many occupations and its decline is deserving of note. Moreover, decline takes place even when the factor of speed is either reduced in importance or eliminated. Jones and Conrad (1933), Miles (1934) and Gilbert (1935) agree, on the basis of their experimental findings, that decline in intelligence takes place even when the factor of speed is eliminated, though Miles contends that speed declines more than power between 20 and 60, while the reverse holds for the period between 60 and 80. Lorge (1936) has investigated the relationship between age and test speed, using three age groups (20-25, 27½-37½, and over 40) equated for score on the Thorndike CAVD test, a power test. When he gave his subjects

the Otis Self-Administering Test, Thorndike Intelligence Test for High School Graduates, and the Army Alpha (all mixed speed and power tests), Lorge found that the older the group, the poorer the performance.

There is some evidence indicating that persons of superior intelligence and education are more resistant to mental decline than others with less native endowments and schooling. It has also been observed that persons who have been outstanding in youth tend to maintain their superior positions into the later decades of life. Miles and Miles (1932) point out that a person who scores in the 93rd percentile on the Otis would be found in the 50th percentile during the eighth decade. On the other hand, a person of average intelligence could be expected to drop to the 6th percentile by the age of 75.

Gilbert (1935) has shown that mental decline is slower in the more intelligent and better educated. Shakow and Goldman (1938) report that persons of very superior intelligence maintain large vocabularies into the eighth decade, while persons of only average intelligence show decline several decades sooner. Jones and Conrad (1933) however, found no tendency for standard deviations to increase in their older groups.

Few studies have dealt with the fate of intelligence in older subnormal individuals. Moore (1929) found that mental loss in idiots begins at an early age and long before adulthood is reached. A longitudinal study of intelligence in older morons has been published by Kaplan (1943). Using the 1916 Stanford-Binet, he found an average decline of only 6.65 mental age months in his group, of whom 9 actually added to their mental age during the period covered by the investigation. The average IQ of his group at the time of the first test was 57.01 and the average age was 41.17 years, with an average interval of 14.95 years between tests. An item analysis of the data showed that vocabulary levels remained almost stationary, while items dealing with lifted weights, memory, and comprehension did not hold up as well.

Whether the claimed better preservation of mental abilities in the brighter and more highly educated is real or merely an outcome of the type of material used in our tests is a

question that remains to be settled. It seems reasonable to suppose that persons engaged in occupations calling for the constant use of verbal skills have an advantage on verbal tests over others who have followed unskilled or mechanical pursuits.

The bulk of the existing evidence indicates that the rate of mental decline is about equal for the two sexes. Conrad, Jones and Hsiao (1933) administered the Army Alpha to 581 males and 607 females living in a rural area and ranging in age between 10 and 60. They found the performance of the females to be slightly superior to that of the males. The females were at a slight advantage on items calling for verbal ability and the males were somewhat better on arithmetic. Jones and his co-workers concluded that the effect of age upon sex differences in intelligence is determined by the composition of the test. In this connection, it is interesting to note that Price (1931) and Carter (1932) have reported lower negative correlations between age and test score in the case of women as compared with men.

E. INTERESTS

Interest trends among professionals have been studied by Strong (1931). Recruiting his 2340 cases from eight professions (engineers, doctors, YMCA secretaries, insurance salesmen, teachers, ministers, writers, and lawyers), he studied men ranging in age between 20 and 59.

He found that those activities which were most preferred at age 25 became even more popular at more advanced ages, while those pursuits which were not liked during early adulthood became even more disagreeable in later life. There was a marked tendency for passive activities to be preferred to active ones in the older age groups, and for group recreation to give way to amusements of a less social nature. In this connection, it may be noted that other studies have shown that this tendency is less evident in older women. Older men were less likely to engage in new activities. Enjoyment of reading increased. There was a significant correlation between age and attitude toward people: people with desirable traits were liked more, and people with offensive characters were liked less, than in early youth. Older people were less venturesome, as

indicated by their dislike for dangerous activities; sedentary activities increased in favor in the later decades. The number of items liked or disliked did not fluctuate markedly during the four decades covered by the study. About half of the changes in attitude took place between 25 and 35, with little or no changes beyond 55.

It is significant that the curves for extraversion and liking for strenuous activity are similar for all eight of the professions studied. However, original differences between the occupational patterns persist and far outweigh age changes common to all, and age differences.

In a more recent volume, Strong (1943) again affirms that occupational and sex differences are more important than age in shaping interests at the adult level, and that there are very few changes in interests beyond the age of 25. Thorndike (1935) has found substantially the same trends reported by Strong.

F. PERSONALITY

Our knowledge of the development of personality during the period of maturity is both scanty and spotty, and most studies have been of the cross-sectional type. The field of personality is so broad that comprehensive investigations are difficult to undertake. A further handicap derives from the existence of wide individual differences at every age level to the very end of life, making generalizations extremely hazardous. Many writers have emphasized that there is a continuity of personality all through the adult period.

Several investigators have noted age trends which are worthy of mention. C. C. Miles (1933) studied personality tendencies, as measured by the Bernreuter personality inventory, in 550 men and women of average and superior ability. She found that age correlated positively with "persistence," but could discover no age relationship for introvert or neurotic tendencies, self-sufficiency or dominance, as measured by the test. Willoughby (1938) found that women were significantly more emotional than men in the entire range between 20 and 70. Women increased in emotionality until about 30, then dropped until about 50, after which they experienced a final rise. Men showed little change with age. Lawton (1942) cites data

indicating that older men are more self-sufficient than older women, and show a greater preference for living alone. Terman and Miles (1936) have found that the attitudes and interests of men incline toward those of women as the men grow older. Morgan (1937) has found some correlation between health and happiness in elderly persons, the coefficient for the women being +.29 and for the men +.43. Health appears to be more important to the men than to the women. Kuhlen (1945) recently has summarized the literature on age differences in personality during the adult years.

Although personality is undoubtedly affected by the physiological changes attendant upon age, the importance of cultural influences cannot be overemphasized. Anthropological studies have shown that the personalities of older persons are greatly affected by the social environments in which they live. Adjustment depends not only on what and how much is lost, but on the role of what is lost in the vital activities of the individual, and the tolerance with which society regards his deficiencies.

It is interesting to note that crime rates decrease in the older age brackets. Although, according to the 1940 census, there were approximately ten million fewer persons in the age group 40-49 than in the category "50 and over," still there were fewer total offenses in 1943 in the older group, and fewer for each separate offense listed. Another statistic which is significant with regard to the personality of older persons is the fact that suicide increases among older white American males as compared with younger ones, while exactly the opposite trend obtains among male Americans of Negro race.

G. OUTSTANDING ACHIEVEMENT

Creative ability in relation to the life span has been extensively studied by Lehman (1936, 1937, 1941). He has come to the conclusion that the greatest number of contributions in science and art are made by men who are on the sunny side of 50.

A survey of the literature on distinguished achievement indicates that peak performances in athletics are generally accomplished by men in their twenties. Scientists, on the average, reach their full power in the early thirties.

Mathematicians, artists, musicians, and writers of prose most frequently do their best work in the late thirties. Astronomers tend to do their outstanding studies in the early forties. Statesmen and military leaders come into greatest prominence in the late forties and beyond.

It should be recognized that studies of outstanding achievement are concerned with individuals of extraordinary endowment who may not even be representative of the general membership of their respective professions, much less of the unselected population. Accordingly, it is possible that these findings are not indicative of the time of production of the best works of less gifted individuals.

Only recently has human life for the average person been extended beyond fifty and many men of genius still fail to reach it. Many of the great geniuses of the past died before they were forty. This fact has not been given sufficient attention in some of the published studies on outstanding achievement.

A large number of factors are involved in the achievement of outstanding success and these vary with the different occupations. Health and physiological factors are all-important in the case of athletes; generals cannot become famous without wars, and promotion is largely determined by procedures derived from precedent; the length of the training period and the state of scientific knowledge are important in determining the period of optimum productivity in science. In other words, factors of a non-psychological nature play a prominent role in determining the volume and quality of achievement.

Motivational factors play an important part in human productivity; the pronounced decline in output reported for scientists, writers, musicians, and artists is to be attributed largely to changes in motivational dynamics. There are numerous instances of opus magnum output in the later decades of life in all of these professions.

It would be risky to predict future peak decades of output in the various occupations on the basis of past experience. The organization of the various occupations is undergoing constant change. Thus, during World War II, the U. S. Air Corps has given stars to several men under thirty. The available evidence seems to indicate that superior achievement is possible

in most of the professions from the twenties until at least the sixties.

H. SUMMARY AND CONCLUSION

Poffenberger (1942) has summarized the results of experimentation on the psychology of maturity with the statement that maximal capacity in essential functions undergoes a decrement of approximately 1 to 1½ per cent a year between the ages of 25 and 55, with an increased rate of loss in the years beyond 55.

It would be foolhardy to assume that the essential facts regarding the psychology of the adult years are now in our possession. Our tentative conclusions are drawn from a limited number of studies, many of which are based on samples not fully representative of age groups in the general population.

Many criticisms can legitimately be directed to some of the studies mentioned in this chapter. There has, for one thing, been too great a dependence on single measures of performance. There has been too little emphasis on the differential effects of age upon persons following different occupations and ways of life. Little attention has been given to the interrelationship of the various factors that have been studied, with the result that many deeper understandings have escaped us. We have dissected the mature without bothering to appraise integrated and living personalities.

It is not always easy to separate cultural from physiological determinants. Presumably, however, those facts of the psychology of aging which are rooted in physiological processes are destined to enjoy a greater permanence than those that rest upon the social environment. It is conceivable that the oldsters of today may not be truly representative of the senior citizens of a generation hence, particularly with regard to those abilities or traits which are affected by sociological and educational influences.

We need to study the trajectories of individual lives. Most of our data are drawn from cross-sectional investigations and suffer from the limitations to which such studies are subject. Until we have followed a large number of careers from early adulthood to senescence, we cannot be certain that the course of decline is uniform for all, or, for that matter, that decline occurs in all individuals and in all functions. It is possible that when our measur-

ing devices become more appropriate, and when we have learned more about the fallibility of our methods of study, that our generalized curves may assume a somewhat different form.

MENTAL HYGIENE.—*Definition and History of the Mental Hygiene Movement.* There is little disagreement to-day on the meaning and function of mental hygiene, even though it is a broad field with rather loosely defined boundaries. This science includes the prevention of inadequate adjustment as well as methods and techniques by which maladjusted individuals are aided in making wholesome adjustments. With the innumerable complex factors constantly mitigating against mental health, it is readily recognized that many of the sciences such as biology, applied psychology, and neurology are inextricably bound up with the prophylactic and meliorative processes. In other words, mental hygiene does not belong to any one field, nor is it obligated to accept the theory, philosophy, or findings of any one field in toto. Since it is fundamentally interested in prevention and restoration, it takes from the sciences primarily those processes which will aid in carrying out its purposes.

The term mental hygiene is not a new one. As far back as 1860 a book had been published by William M. Connell under the title of *How to Enjoy Life, or Physical and Mental Hygiene*. Mainly through the efforts of the National Committee for Mental Hygiene and its allied organizations the term has gained a wider significance.

The dramatic story of the beginnings of the

mental hygiene movement stems from the year 1908, when a young man, Clifford Beers, developed a serious personality maladjustment and became a patient in both public and private hospitals for the insane. Upon his successful recovery he was determined to devote the remainder of his life to improving the treatment and conditions of the mentally ill. The story of his commitment to various asylums and the harsh treatment which he received is candidly told in his book, *A Mind That Found Itself*, published in 1908.

This publication was the beginning of the mental hygiene movement which has spread to almost every country on the globe. The first State Committee for Mental Hygiene was organized May 6, 1908 in Connecticut. A year later the National Committee for Mental Hygiene was organized. The movement spread so rapidly that by 1919 it had attained international status and the International Committee for Mental Hygiene was established. The first International Congress on Mental Hygiene met in Washington, D. C., in 1930 and 50 countries were represented.

The story of the rapid growth of the mental hygiene movement reads like a fairy tale. Its accomplishments have been far greater than its founder ever dreamed. These achievements, however, have not been realized without overcoming a great many obstacles. Of necessity during the first few years, much time and energy were spent establishing a sound basis, financial and social, for a future program.

Originally the expenses were met by contributions from interested members in the field of mental hygiene, and financial support which Mr. Beers gave it indirectly through loans made to him personally.

In the beginning the activities of the National Committee for Mental Hygiene were directed toward the amelioration of the conditions in the hospitals for the insane. Many local, state, and national surveys were conducted which disclosed the intolerable conditions existing in such institutions. These surveys also made available for the first time pertinent data regarding the resources for the care and treatment of the mentally ill.

The presentation of these facts aroused public opinion to the extent that legislative changes enabled the recommendations to be put into effect. Through the use of the survey tech-

nique, information with regard to conditions existing in the penal institutions was obtained and reforms were brought about. Steadily but surely the field broadened to include the school and the community. Each step in the development of the program has approached more closely the origins of maladjustment. The mental hygiene movement has proceeded from the stage where the attention was directed primarily toward the humane treatment of patients in mental hospitals, to the level where emphasis is placed on the amelioration of conditions and the prevention of maladjustments.

Provision for Caring for the More Seriously Maladjusted. As has been suggested, one of the first objectives of the mental hygiene movement was to bring about a reformation in the attitude toward and the treatment of the mentally ill patients. This was a very difficult task and in order to make any headway it was necessary to educate both the scientist and the layman in the care and treatment of the mentally ill, and in the prevention of mental illness. As the movement grew and the scientific information became better organized, it also had the task of educating the public in the more appropriate use of terms. In this respect a great deal of progress has been made. The "lunatics" and the "crazy" people are no longer bound in chains and placed in "madhouses" or "insane asylums." Even the use of such terms as "crazy" or "insane" to designate the mentally ill is becoming obsolete. Some of the newer terms such as psychiatry, psychiatrist, psychiatric institute, sanitarium, retreat, psychopathic hospital are more or less familiar to the public. Recently the use of the term *psychiatric* has been questioned because of the possible misinterpretation of the causes of mental disease. A. J. Rosanoff has suggested *cerebrology* as a more suitable and scientific term. With all these accomplishments the original goal has not yet been reached. A great many people shudder at the thought of the existence of mental illness in the family. They must be educated to the point of view that mental disorders are the products of abnormal, unhealthy ways of living. A psychosis or neurosis is a maladjustment of the whole personality and in treating it consideration must be given to all the various causes including the hereditary, social, economic, physical and emotional. A very large percentage of the mentally ill never require commitment to an institution.

The unbalanced personality that has not yet become neurotic or psychotic but is badly adjusted to its environment is being given more attention. Such agencies as child guidance clinics, mental hygiene clinics, social adjustment centers, institutes of family relations, personnel departments in school, college, and industry are positive aids in developing well-balanced personalities.

The modern hospital for mental illness utilizes a great variety of techniques in the treatment of its patients. It attempts to give each patient the benefits of the latest and best scientific research in the field. The hospital is no longer a place for merely keeping the patient confined. It is a specialized institution where a definite positive program of analysis and treatment is followed. When a person is brought to a hospital for treatment an effort is made to secure an anamnesis, which gives as complete a description as possible of the patient not only during his mental illness, but also during his previous normal state. Also, upon entering the hospital the patient is given a thorough physical examination, since the mentally ill are not immune to the physical illnesses which are found among the general population. As a matter of fact, certain diseases are somewhat more prevalent in patients with mental illness than in other groups. Treatment is begun only after a thorough diagnosis has been made.

Probably the most important phase of the treatment is to make the hospital community an exceptionally pleasant place in which to live. Any patient will find in this environment some work either closely allied to the vocation he once followed or to a hobby in which he might have had an interest. It has been found that wherever it is advisable, considering the health of the patient, the "work cure" is much superior to the "rest cure" as a form of treatment. Therefore, a large percentage of the "guests" participate in some form of occupational therapy. In some of the less modern hospitals, chair-caning, basketry, weaving, and the like are still being continued. In the more modern institutions the "guests" participate in those activities and interests which can be carried on after they leave. Here we find the "guests" writing novels, landscape gardening, painting and sculpturing, learning to make dresses, taking bridge lessons, studying current events, taking university extension courses, and taking music lessons. Be-

sides occupational therapy many other kinds of therapy are appropriately applied to each individual. Some of the other more important treatments are hydrotherapy, electrical therapy, pyrotherapy, drug therapy, physiotherapy, suggestion therapy, psychoanalysis, surgery, and dietetics. Also, a great deal of attention is given to the social program. The patients organize their own dramatic clubs and musical organizations, and give programs which the others may attend. Likewise they may listen to the radio, attend motion pictures or engage in athletic activities of various kinds. Church services are conducted regularly and in most hospitals library facilities are provided.

The Contributions of Mental Hygiene. Data show that approximately one person in twenty-two becomes a patient in a mental hospital in a single generation. This fact alone reveals the importance of the meliorative phase of the mental hygiene program. It is necessary that the 500,000 psychotics have some place to go where they may receive treatment in order that they again may assume their rightful place in society. The neurotics form a much larger group which needs treatment. These adult individuals seem unable to develop a stable personality. A relatively small number of these neurotics are so seriously maladjusted as to be committed to an institution. However, they are in constant conflict not only with their associates but also with themselves. This condition is a source of much unhappiness and individual inefficiency. Certainly they were not born neurotics but this neuroticism is a result of many experiences in childhood that have had a detrimental effect on the developing personality. Every child has certain fundamental needs which are very similar to those of every other child. However, every child possesses characteristics that make him different from every other child. These differentiating factors make it extremely difficult if not impossible to satisfy these needs in the same ways. Ignorance or unwillingness on the part of parents to recognize the importance of forming wholesome habits in early childhood may account for a great deal of maladjustment later in life. The amount of emphasis placed upon the formal curriculum in a competitive atmosphere motivated primarily by marks and promotions, and the fear of failure instilled by teachers who lack skill in understanding children have no doubt contributed their share of maladjust-

ment. The positive purpose of mental hygiene is therefore, to help the child satisfy his basic needs in a socially acceptable manner.

The parents, first of all, must provide proper physical care and protection. While this may not be essential, such care is a basic item in the development of a wholesome personality. Any illness which the child may have or any physical defect which he may possess militates against his developing mentally healthful behavior patterns. It is under these conditions that the parents may over-protect him, and thus cause him to be too dependent or to develop a fear of further injuries or illnesses. One possible result of over-emphasis of the problems of health is the hypochondriac who exaggerates his illnesses or even believes he is ill when he is not. This is also a chance for the child to feign illness when he has some difficult or disagreeable task to perform. The parents must realize the importance of forming socially acceptable habits very early in life. Sufficient experimental data exist which show that these early behavior patterns persist with a great deal of tenacity. Two other important home sources of behavior problems are those of the broken home and those in which the home atmosphere is mentally unhealthful. Every child has the right to two parents living together in a congenial intra-family relationship.

From the writer's point of view it is the function of the school to carry out both the meliorative and prophylactic phases of the mental hygiene program. It is extremely difficult to determine just where prevention leaves off and treatment begins. This is especially true when we think in terms of the minor maladjustments and when we realize that no human being can understand every child perfectly. Childhood offers the best opportunity for constructive mental hygiene and therefore the schools should recognize certain principles derived from the best research in the field of mental health. It should be remembered that mental hygiene is a way of life, an attitude, a point of view, which has as its goal a wholesome, happy, well-balanced life. This atmosphere should permeate the entire school system.

It is only natural that teachers want to see their pedagogical labors achieve their maximum effectiveness and this effectiveness is exhibited most vividly in the more academic subjects. They should, however, seek to educate the total

personality. They should develop in their pupils the most mature expression possible of intellectual capacities and emotional responses. The slighting of any one or more phases may deprive the child of part of his education and may develop a warped personality. Therefore, the curriculum should be constructed so as to make provision for the all-around growth and development of the child. The knowledges and skills should be used primarily as means to ends rather than ends in themselves. The curriculum should be sufficiently broad in scope and flexible in function to meet the needs and interests of all the children.

The atmosphere of the classroom is another important phase which the school should consider. It should be congenial and friendly, and the cooperative spirit should dominate at all times. The child should feel secure and at ease as he participates in the various activities. The home and the school are the two centers where the child should learn to live and work cooperatively. This whole problem of classroom atmosphere is tied up very closely to the one in charge of the children—the teacher. It is impossible to expect to have mentally healthful children unless the teachers possess well-balanced personalities. There has been a great deal of discussion in the last two decades concerning the importance of the selection of teachers and some headway has been made. Even though the personality of the teacher is the most important single factor in the educational process, it has been only recently that any attention has been given to this phase of selection, except for the elimination of people with the more bizarre deviations. Most emphasis has been placed on the knowledge of the subject matter and methods of presenting that knowledge to children. In the last few years a few meager attempts have been made to consider the factor of wholesome adjustment in the selection and certification of teachers. However, no long term studies have been made to determine the validity of the techniques used. From a mental hygiene point of view, the future teacher must possess a well-balanced personality, a functioning knowledge and understanding of human behavior and must be convinced that the adjustment of human beings to social living transcends factual knowledge or techniques of presenting that knowledge to children, important as these may be. This implies that the

teacher of the future must be recognized as a human being. He has need for a feeling of security, for recognition of personal worth and accomplishment, for affection, and for favorable conditions of work as well as living.

A third important phase which the school must consider is that of appraising development. The school no longer can simply evaluate pupil progress in terms of subject matter learned and skills acquired. The results of any appraisal must be considered in the light of the child's general mental maturity, his physical condition, and his social and economic background. Every evaluation should be made with the primary purpose of helping the child. Tests and examinations are not the only ways for measuring pupil progress. Observation of how the pupil goes about his work, how he cooperates and plays with other children, and a knowledge of his attitude toward school in general may be even more important than knowledge of the grade level on which the child is reading. In any modern appraisal program the teacher must possess the diagnostic point of view. He must determine the *causes* of the difficulty and then apply appropriate treatment.

Mental hygiene plays an important part not only in the home and school but it operates in every walk of life. In industry provision is being made for better working conditions. More cordial relations are being fostered between employer and employee. Problems arising between the administration and the workers are being discussed by representatives from each group. Analyses of the strengths and weaknesses of the worker are being made in an attempt to place him where he is most efficient. Personnel experts are being employed to aid workers in adjusting some of their more personal problems. The industrialist has learned that a happy and well-adjusted worker is a producer.

Possibly in no other field have the principles of mental hygiene been applied more avidly than in World War II. Beginning at the induction station and continuing until the service man received an honorable discharge, an attempt was made to decrease the number of neuropsychiatric casualties. Especially after the return of the service men was it necessary for everyone to apply the basic principles of mental hygiene.

One may go on endlessly and point out the various fields of endeavor toward which the

principles of mental hygiene may apply. The ones discussed give an idea of the progress the mental hygiene program has made since its inception less than forty years ago. They also should present a challenge for a wider application of its principles in the future.

MORALE.—Morale is a term which comes into prominence during crises when the conditions to which it refers are painfully absent or conspicuously present. These conditions were defined by a committee of psychologists meeting under the auspices of the National Research Council in 1940. The definitions, as reported by Child (1941), were as follows:

I. (The individual-organic emphasis.) The term *morale* refers to a condition of physical and emotional well-being in the individual that makes it possible for him to work and live hopefully and effectively, feeling that he shares the basic purposes of the groups of which he is a member; and that makes it possible for him to perform his tasks with energy, enthusiasm, and self-discipline, sustained by a conviction that, in spite of obstacles and conflict, his personal and social ideals are worth pursuing.

II. (The group emphasis.) *Morale* refers to the condition of a group where there are clear and fixed group goals (purposes) that are felt

to be important and integrated with individual goals; where there is a confidence in the attainment of these goals, and subordinately, confidence in the means of attainment, in the leaders, associates, and finally in oneself; where group actions are integrated and cooperative; and where aggression and hostility are expressed against the forces frustrating the group rather than toward other individuals within the group.

III. (Emphasis on individual-within-the-group on any specific occasion.) Given a certain task to be accomplished by the group, morale pertains to all factors in the individual's life that bring about a hopeful and energetic participation on his part so that his efforts enhance the effectiveness of the group in accomplishing the task in hand.

In this discussion morale will be used in a fashion similar to the "group-emphasis" above to refer to the degree to which the individual members of any defined group are united and motivated in their efforts to achieve a common goal. Technical usage of the term morale should involve the following considerations: (1) the particular group to which the term is applied; (2) the degree of unity within the group; (3) the strength of motivation present in the group; (4) the specific goal toward which the efforts of the group are directed.

Team morale, employee morale, military morale, enemy morale, and civilian morale, refer to the morale of particular groups with respect to particular goals. Unity within each of these groups implies a willingness to cooperate among the individual members. The determination with which the group pursues the goal is dependent upon the strength of motivation present. The goal itself, for each of these groups, may be positive or negative in character. A group, for example, might have as its positive goal the attainment of a certain production total. Another group might be organized around a negative goal such as the avoidance of defeat.

Morale, as this discussion indicates, is a matter of degree. High morale depends upon the degree of unity and the strength of motivation present within the group. Low morale may be the result of lack of unity, i.e., unwillingness to cooperate, among members of the group. In an industrial plant, management and employees may be agreed upon a stated production goal but may differ in their beliefs as to the best

method of achieving the goal. In the absence of unity between the two groups, regardless of the fact that they have a common goal and may both be equally determined to achieve the goal, plant morale may be low. Low morale may also be the result of relatively weak motivation. A group may be united in its efforts to achieve a common goal, but a strong desire to attain the goal may be lacking.

Any group may be conceived as having a social structure. The social structure defines permissible patterns of behavior and other patterns which are not. These behavior patterns in turn become associated with values, emotions, and sentiments. A social structure once established tends to have a certain stability, i.e., it is resistant to change. If a social structure permits satisfaction of desires and motives of the individual members and also serves to unify the efforts of the group as directed toward some common goal, the structure is said to be in a state of equilibrium or balance. It is under these conditions that the morale of a group is at a maximum. If the social structure is such that it demands more in the way of sacrifice of individual motives and ambitions than the individual members are willing to yield, then morale declines. If an athletic team, for example, demands too many sacrifices, then individual members of the team are apt to violate the prohibitions; the unity of the group is destroyed and morale drops. In a similar fashion if a nation at war demands sacrifices beyond the maximum which the people are willing to make in the interests of achieving the common goal of victory, there is also a lowering of morale. On the other hand, if the social structure does not necessitate some surrender of individual desires, then the unity of the group may suffer with a consequent lowering of morale also.

Various lists of the components of morale have been made, but these lists are at best shrewd guesses. With respect to military morale they have included such things as: freedom from anxiety, sense of pride, confidence, sound health, good food, and so forth. When we stop to consider that some military units have maintained high morale in the absence of many of the factors usually contained in such lists, we must acknowledge that the exact components of military morale are not known. One factor, however, which has appeared in both military

and industrial surveys of morale, is that of leadership. Cooperation and strong motivation seem to be characteristic of groups which have satisfactory relationships with leaders.

One survey of military morale reported in *Psychology for the Fighting Man* (1943) revealed that high morale was associated with:

1. Leaders who were competent and had the necessary abilities which their positions as leaders demanded.
2. Leaders who were able to make decisions promptly when required to do so.
3. Leaders who had the interest and welfare of the members at heart.
4. Leaders who made things clear to the members; who gave orders in a manner that showed every member exactly what was expected of him.
5. Leaders who were impartial and did not play favorites with individual members.
6. Leaders who rewarded members by judicious words of praise or by some other form of recognition when a job had been successfully executed.

Similar surveys of industrial morale indicate that rest periods, wages, ventilation, temperature, lighting, and other physical factors which were once considered of great importance in determining morale by industrial engineers, do not deserve the stress they were formerly given. The work of Roethlisberger and Dickson (1943) and Mayo (1933) indicates that human relationships in industry, as in the army, are of far greater significance as far as morale is concerned.

The athletic teams of coaches such as Knute Rockne and Paul Brown, who have observed the importance of human relations in dealing with the members of their teams, are known for their high morale in time of defeat as well as in victory. The extent to which the German peoples' confidence in the leadership of Adolf Hitler kept them unified even in the face of defeat and extreme hardships is a factor which may eventually be analyzed.

During times of crises such as floods, depressions, earthquakes, wars, and other disasters, morale becomes a subject of national importance. That is because the individual efforts of all members of a country must be united if the emergencies of the situation are to be met. A

war obviously requires that the individual citizens be united and determined in their efforts to defeat the enemy if the war is to be successfully carried through to completion. Civilian morale must be maintained at a high level if production goals are to be met, bonds are to be bought, and rationing and other wartime regulations are to be willingly accepted. Morale of the armed forces is of vital importance if military operations are to be successful.

In modern war also, with the development of radio and other means of communication, the state of morale of one country is open to attack by another. If it is possible to destroy the unified efforts of a country or to weaken its determination to wage war by means of propaganda, military operations of that country are impaired. The German propaganda theme of World War II, "divide and conquer," expresses the point. Most governments maintain during war periods agencies or departments whose function it is to look after the state of morale on the home front and to plan systematic attacks upon the morale of enemy countries. Even within the armies, units have been established to wage similar psychological attacks upon the morale of opposing combat troops.

Morale can be estimated insofar as it is possible to discover the degree of unity of effort within a given group and the determination of the group to achieve a common goal. Allport (1942) has provided an extensive list of sources of evidence pertaining to morale. Responses to opinion polls on such items as confidence in leaders, willingness to sacrifice, and agreement with government policies are indicative of national morale. Civilian morale might also be estimated by the degree of participation in salvage programs, blood contributions, bond buying drives, and other activities of national concern. Analyses of the press, including letters to the editor, columns, features, and editorials may provide additional information. Evidence concerning industrial morale may be obtained from data on strikes, labor turnover, and production, as well as from surveys of opinion. In the armed forces interviews and opinion polls, and statistics on desertions, AWOL, suicides, disciplinary actions, and malingering, might be used as sources of information concerning morale.

MOTIVATION. — *Practical importance.* Questions concerning motivation arise in every field of applied psychology. In educational psychology there are problems concerned with the relative effectiveness of praise and reproof, reward and punishment, success and failure, competition and coöperation; of working with or without knowledge of results or a definite goal or enthusiasm. In clinical psychology and psychiatry motivational problems center around the explanation of frustrations and conflicts and such symptoms as tics, amnesias, functional paralyses, dissociations. Legal psychology carries a heavy load of motivational concepts—intent, choice, will—but too often does not interpret human conduct according to modern psychological principles. In the eyes of the law the difference between murder and manslaughter is one of intent or motive. In industrial and military psychology problems of motivation relate to morale, effectiveness of different systems of payment and hours of work, the psychology of participation, efficiency of work as related to illumination, temperature, distraction, music, and other environmental factors. In personnel psychology and the art of counseling, the aims, interests, and evaluative attitudes of an individual are as basically important as his skills and achievements. In all these and other areas a workable psychology of motivation is essential.

Definition. Motivation is the process (a) of arousing or initiating behavior, (b) of sustain-

ing an activity in progress, and (c) of channeling activity into a given course. Broadly considered, the analysis of motivation must take account of all factors which arouse, sustain, and direct behavior.

The concept of motivation is thus a very broad one. It is not so broad as psychology itself, however, since psychological explanation includes consideration of both non-motivating and motivating factors.

The nature of the motivational process is highly complex. Its underlying biological bases will be considered first, after which the social and experiential aspects will be examined, theoretical implications following.

Equilibrium and bodily need. The single most basic biological factor in the motivation of behavior is the necessity of meeting the bodily requirements for survival.

In 1859 Claude Bernard described the internal environment of the body in which the cells exist. He demonstrated that in mammals the physicochemical properties of this internal environment vary within fixed limits and that variation outside of these limits endangers life. More recently Cannon (4), after a series of careful experiments, confirmed and extended the views of Bernard. Cannon coined the term *homeostasis* to designate a relatively constant physicochemical state within the body. The relatively constant states of the body are maintained through the cooperative action of the brain and nerves, heart, lungs, skin, kidneys, spleen, and other organs.

This doctrine of Bernard and Cannon provides a workable basis for defining the physical needs of an organism. In order to maintain homeostasis, an organism must obtain from its environment definite quantities of oxygen, water, fat, protein, carbohydrate, minerals, and certain of the vitamins. Further, the body must be maintained in temperatures within a definite range. The waste products of metabolism must be eliminated. Sleep, rest, and activity must be obtained. A *need* is a requirement for maintaining homeostasis and thus ultimately a requirement for survival itself; or for growth, reproduction, normal activity, a sense of well-being, and freedom from disease.

In his Harvey lecture, Richter (19) pointed out that the behavior of man and animal is directed toward the maintenance of a constant internal environment. This thesis is supported

by much evidence. A single illustration will suffice: Normally the pituitary and thyroid glands, in cooperation with other organs, regulate the internal temperature of the body. If these glands are surgically removed, rats lose their ability to produce adequate amounts of bodily heat. The deficiency is corrected for in the animals' behavior by a greatly augmented tendency to build nests out of strips of paper. The nests conserve bodily heat just as clothing or a dwelling does for man.

The theory that behavior is directed toward the maintenance of homeostasis has been extended by psychologists to include the maintenance of internal equilibria which are not essential to survival. Thus Freeman (7), with a bias toward *Gestalt Psychology*, has defined motivation as a condition of disequilibrium within an organism which leads to action for the restoration of equilibrium. Motivation, he says, is not the stimulus nor an object sought but a state of disequilibrium within the organism. The sight of a piano, for example, does not compel the musician to play. Before he performs there must be an inner desire to play. The desire is a state of disequilibrium within the bodily mechanisms which regulate behavior.

Freeman's theory suggests the complacency theory of Raup (18) and the closure theory of Koffka (13). These theories all agree in that they emphasize the basic importance of disequilibrium and the restoration of equilibrium through behavior.

The view that the rôle of behavior is to meet the needs which restore internal equilibrium (homeostasis, complacency, stability, balance) is satisfactory as far as it goes. The view must be supplemented, however, by an objective description of those bodily processes through which needs are met and equilibria restored.

Biological drives. The term *drive* commonly refers either (a) to persistent behavior which is typically goal-directed or (b) to the internal stimuli which release such behavior. For clarity these two main aspects of drive will be called *behavioral drive* and *physiological drive*. There is also a *conscious* aspect.

A behavioral drive is illustrated by the persistent attempts of a man lost on the desert to find water. This dominant drive motivates subordinate activities which lead up to the goal-response of drinking. The goal-response re-

duces the drive and brings the episode in behavior to a close. In this instance the physiological drive is the persistent stimulation of nerves due to the dry condition of the tissues in the throat and mouth. This stimulation also underlies the unpleasant pressure-pain which the thirsty man experiences.

The behavioral aspect of drive has been emphasized by Warden (26), Tolman (23), and Skinner (21). Warden states that a drive is an aroused reaction tendency which is characterized primarily by the fact that the activity of an organism is directed towards or away from some specific incentive, such as food, water, animal of the opposite sex. He makes it clear that the term *drive* does not refer to the physiological state or system aroused either by an incentive or by a deprivation of some sort. The term refers directly to the behavioral tendency resulting from the internal arousal.

Tolman, following Craig, subdivides the primary drives into two groups: appetites and aversions. An appetite is observed as an agitated state of behavior which persists as long as a certain stimulus-object is absent. An aversion is also observed as a state of agitation but it is one which continues as long as a certain stimulus-object is present. Appetites are cyclic; they appear and disappear. Aversions, contrastingly, depend upon external circumstances which arise irregularly and unpredictably. For example, if an enemy appears, the aversion is revealed by aggressive behavior. According to Tolman, there are two main human aversions: fright, which leads to avoidance, and pugnacity, which leads to attack.

Skinner holds that psychology is a pure science of behavior without physiological entanglements. For him a drive is defined as a hypothetical organic state. A drive is assumed to exist on the basis of a relationship between observed behavior and certain laboratory operations. For example, after a rat has learned to press a lever to obtain pellets of food the rate at which he presses this lever can be shown to vary with the period of food deprivation. The relationship between rate of pressing the lever and period of deprivation can be described by a graph or an equation without postulating any hunger state. It is convenient, however, to postulate a hunger drive within the organism.

The physiological aspect of drive, on the

other hand, has been emphasized by Dashiell (5). He defines a drive as a condition within an organ or tissue by which an animal is set into activity. This view of drive stresses the bodily sources of stimulation which release the energy of behavior. Goal-directed behavior is *driven* by these internal stimulations.

Young (28) has distinguished between primary and secondary drives on the basis of their internal or external origin. A primary drive, such as micturition, is one for which the bodily mechanism arousing the characteristic behavior has been objectively described and differentiated from the bodily mechanisms of other drives. A secondary drive, such as flight from an enemy, is one which originates in the environmental situation and for which no characteristic bodily mechanism has been discovered.

The following drives can be listed as primary motivations: hunger for food, thirst for water, the urge for air, the drive to maintain an optimal bodily temperature, the drive to defecate, the drive to micturate, the drive to rest after protracted exertion, the drive to be active after prolonged inactivity, the drive to sleep following protracted wakefulness, the drive to copulate, and a female drive to nurse the young. The list is conservative and will probably be revised by extension and subdivision rather than by eliminating the drives listed.

For every primary drive there is a characteristic goal-response which meets a bodily need. Thus, for fatigue the goal-response is resting; for thirst the goal-response is drinking; for the internal sexual drive the goal-response is copulating. The primary biological drives can be described either in terms of internal bodily mechanisms or in terms of the characteristic goal-responses which meet needs and restore homeostasis.

In addition to the primary biological drives there are other organic and environmental factors which play a dominant rôle in behavior. In an important study Anderson (2) gave male albino rats a variety of tests of motivation and learning. The test scores were intercorrelated and factor analyses made. He found evidence that the traditional drives of hunger, thirst, and sex operate to determine individual differences in performance. More important than the traditional drives, however, were several factors of broad scope. Some of these broad factors (the

general level of activity; emotionality) probably have an organic basis. Other factors (exploration; aptitude for a particular apparatus) depend upon the particular environmental situation. Further studies of this type are indicated.

Internal and external determinants of behavior. In all purposive behavior there is both an internal and an external aspect. Some activities, such as food-seeking by a hungry organism, are motivated mainly by internal stimulations. Others, such as exploring a novel environment, are determined mainly by external conditions. Some behavioral drives have both internal and external determinants. For example, the sexual drive rests upon an internal bodily state and the presence of a mate in the environment.

The extent to which internal and external factors determine behavior varies with habituation. For example, hunger originally is an internal condition of the organism. If an animal satisfies his hunger over a long period of time in a relatively constant environment, the patterns of behavior which lead to the reduction of hunger come to be aroused by environmental stimulations. Thus a laboratory rat may learn to reduce the hunger drive by running a maze, escaping from a problem-box, discriminating between visual forms, crossing an electric grill, digging through sand, running back and forth between food and starting-box, pressing a lever, jumping a gap, or through other activity that leads to food. After he has learned to operate the gadgets of the laboratory he will operate them (at least for a while) even when satiated.

Anderson (3) has shown that patterns of behavior originally motivated by physiological drives become, through conditioning, more and more controlled by external conditions. He has called this the *externalization* of drive. Externalization of drive spreads from one stimulus-object to another until finally a great many stimulus-objects associated with the reduction of hunger come to arouse the instrumental activities. If externalization were complete, the behavior which leads to feeding could be aroused almost in full strength by presenting the environmental conditions in the absence of bodily hunger. In a word, behavior originally motivated by internal determinants becomes increasingly controlled by external determinants.

From another point of view the process of learning can be described as the *internalization*

of the environment. By this is meant that the neural organization of an individual is developed for the reduction of drives in particular environments. In a real sense a man learns to meet his biological needs according to the rules of his own society. The socially approved patterns of behavior are internalized in terms of habit-organization and attitude.

Social incentives and motives. Social incentives are the spurs and checks to behavior which originate within the social environment. Social motives, in the narrower meaning, are the aims and purposive determinations of an individual living in a social world.

A great many experiments have been carried out upon social *incentives*. The typical aim of such experiments has been to compare the relative effectiveness of such incentives as praise and reproof, reward and punishment, competition and coöperation, and so on. For illustrative purposes brief references to some of this work are given below:

Hurlock (12) found that the consistent use of praise was more effective than reproof as an incentive for school children. But in a more recent study Schmidt (20) concluded that neither praise nor reproof can be singled out as the superior incentive. The relative effectiveness of these incentives depends upon the social situation, especially upon the personality of the experimenter.

Hamilton (9) compared reward and punishment. With one group a bell was sounded as a reward for the correct adjustment of a Galton bar and with another group the same bell was sounded as a punishment for errors. The experiment was planned so that reward and punishment would be given with about the same frequency. Although there was slightly more improvement with punishment than with reward, the difference between these incentives was not significant. Muenzinger (15) obtained a similar result with rats on a brightness discrimination problem. With one group of animals a moderate electric shock was used as a punishment for errors and with another group the same degree of shock was employed as a mark of correct responses. The shock-wrong group learned the discrimination slightly faster than the shock-right group but not significantly so. The shock, however, had a general motivating effect, clearly apparent when the shocked groups were compared with a non-shocked control. From both

of these studies, different as they are, we may conclude that punishment and reward are about equally effective *provided the physical characteristics of these incentives are the same.*

The experiments upon competition and coöperation have been summarized by Vaughn and Diserens (25) and by Murphy and Newcomb (26). On the basis of these reviews it may be said that individuals respond differently to competition; some are facilitated and others inhibited or disrupted by competitive work. The capacity to compete or to coöperate appears to be present in all human beings; but some societies tend to develop competitive and others to develop coöperative behavior.

In general, the experiments upon social incentives suggest that we cannot make absolute comparisons of praise and reproof, reward and punishment, competition and coöperation, etc., if these incentives are abstracted from the concrete situation in which they exist. The effectiveness of these incentives is relative to the kind of social situation in which they are embedded. Every comparison should be qualified by the phrase "in such and such a situation."

Social motives—specific determinations to act, social aims, and purposes—originate in the social situation. For example, when a mother instructs her child to go to the store and buy a loaf of bread her words build up a mental set which directs and energizes behavior. A suggestion or a command, whether given by word or gesture, may build up in the individual a specific determination to act.

Some purposive determinations refer to remote social goals. When a young man has determined to study medicine this determination persists over a period of years. It underlies much of his daily activity. For long periods of time, however, this determination may be latent, not apparent in behavior.

A latent determination to act differs from a latent attitude or habit in that it is more specifically goal-oriented. An attitude is a readiness to respond positively or negatively to a psychological object and in a particular manner. There are attitudes of love, hate, fear-avoidance, resentment, disgust, amusement, inferiority, self-confidence, etc. Although such attitudes are latent much of the time, they are aroused in the appropriate social situations.

One particular group of attitudes is of special psychological importance: the attitude toward

one's self. Through inter-personal behavior an individual comes to understand his status in the group, and the rôle he plays; he learns how important or unimportant he is in a variety of inter-personal relationships. He develops attitudes of assurance and self-confidence, based upon success, or attitudes of inferiority, based upon failure. The attitudes of self-regard have a very marked effect upon the efficiency of his performance.

In addition to attitudes the individual, through inter-personal behavior, acquires habit-organizations. He learns to speak his native tongue. He learns to dress, to eat, to court, to hunt, to sleep, to play, to work, in accordance with the behavioral patterns of his group.

Habit-organizations differ from attitudes in that the former simply exist as bits of psychological organization. Attitudes are predispositions to react *towards* or *against* some psychological object. And social motives are still different in that they are goal-oriented determinations to act.

Habit and drive. Through a process of learning a man acquires the ability to add and subtract, perhaps, to drive an auto, to play a violin. He carries around with him these "possibilities of action," as Woodworth (27) called them. Motivation was necessary for the original learning of these activities. Motivation selects from the potential activities the one to become actual in behavior. Motivation is always a *contemporary* process, implying a release of energy at the time behavior occurs. Latent habit-organization does not motivate; it merely predisposes the individual toward certain patterns of behavior.

A habit has two main aspects. From one point of view it is an acquired pattern of behavior such as typewriting a familiar word. From another point of view it is the acquired neural organization which is the basis of habitual behavior.

If an organism performs some act which reduces a drive, this act is more likely to be repeated in the future when the organism is placed in a similar situation. For example, if a hungry rat obtains a pellet of food by pressing a lever, he is more likely to press the lever the next time he is placed in the apparatus. Pressing the lever is an instrumental act which brings food. The food is a reward which reduces the drive. The eating of food reinforces the instru-

mental act, *i.e.*, increases its probability of occurrence. The strength of a habit depends upon the number of previous reinforcements and their distribution in time.

If the reward is withheld, the habit is weakened. Eventually it is extinguished. The number of non-reinforced responses required to extinguish a habit varies with the number of previous reinforcements and also with the strength of the drive. Hull (11) has shown that if a rat has learned to obtain a pellet of food by pressing a bar, the probability that this conditioned response will occur is dependent upon two main factors: habit strength and strength of drive (measured in terms of the period of food privation). Practically, this means that in predicting behavior one must take account of previous training as well as motivation.

Hull's work implies that if the strength of drive is reduced to zero, through satiation, the conditioned response will still occur when the animal is placed in the accustomed situation. This implication has been confirmed in several experiments.

The doctrine of functional autonomy. Allport (1) has argued that a habit may become self-motivating, or functionally autonomous. As a man advances from infancy to maturity the character of his motivation alters so radically that we may speak of adult motives as having *supplanted* those of infancy. Adult motives differ widely from person to person. The motivation of each adult is unique. With Leo Tolstoy, for example, the *Leitmotif* was the simplification of life. A person who knew this dominant motivation could predict Tolstoy's probable reaction to certain types of situation. But any attempt to attribute Tolstoy's personality to extrinsic drives or instincts would be futile. Behavior becomes functionally autonomous.

The doctrine of functional autonomy clears the way for a dynamic psychology of traits, attitudes, interests, and sentiments. These, Allport believes, are the ultimate and true dispositions of a mature personality.

In appraising this doctrine we should note that nothing is added to the facts by the statement that a bit of behavior is autonomous. One is not greatly enlightened by the statement that "Sammy goes because he goes." On the positive side, Allport's doctrine is a challenge to psychologists to reveal the actual motivations of acts which are seemingly autonomous. If we

start from the assumption that all behavior is motivated at the time it occurs, then some motivation must be present even in the most autonomous or habitual performance. The problem for the psychologists is to discover what motivation is actually present.

Postural set and neural readiness. If a child is instructed to repeat the letters of the alphabet, starting from *A* and going to *Z*, the chances are that he will do so. The instruction is motivating in that it builds up a determination to act in a specific manner and sustains the verbal sequence of behavior. Such a serial habit is possible, however, only after a period of learning. The well learned habit goes along so smoothly that it seems to be self-motivating. When the child pronounces the letter *A* the proprioceptors are excited in a characteristic pattern which immediately precedes the next unit of response: pronouncing the letter *B*. One unit of the serial habit comes, through conditioning, to excite the next and so on through the alphabet from *A* to *Z*. The proprioceptive pattern of stimulation is an important part of the total motivation but this alone could not initiate and sustain the serial habit. The determination to repeat the alphabet is essential.

Under some circumstances a determination to act in a specific manner is outwardly observable as a postural set of the organism. For example, when a runner is toeing the line and awaiting the gun his stance is a preparation for starting the race. The firing of the gun simply releases behavior for which the runner is prepared.

Frequently, however, the postural set is covert. A resolution to keep an appointment downtown, for example, may not be apparent in behavior. The resolution is an internal set which regulates the course of impending behavior.

There are two main hypotheses concerning the way in which an organism carries a covert determination from one time to another. First, such a determination may be carried by actual tension in some group of muscles, skeletal or smooth. Second, it may be carried as a purely neural readiness without any tonic change in the muscles.

To illustrate the reasonableness of assuming a neural readiness consider the college professor who has prepared a lecture to be delivered the next day. After some study he is mentally set

for the talk. He has prepared some notes which can furnish cues for the arousal of mental sets and the prepared words of the talk. The cues from the notes are part of the total motivation during the presentation of the lecture. These cues activate a latent readiness to respond. It is difficult to imagine how the complex preparation to deliver a lecture could be carried in terms of muscular tension, especially in view of the fact that between preparation and delivery all of the professor's muscles were relaxed in deep sleep. Further, these same muscles were utilized in a great variety of ordinary activities.

A neural readiness is latent, non-motivating, from one time to another. External stimulations activate this readiness and build up a characteristic tension. The tension stimulates the proprioceptors and thus furnishes an important part of the total motivation.

In this connection reference might be made to a view expressed by Stagner (22). In discussing functional autonomy he argued that each habit has its own characteristic drive. The drive becomes apparent when an habitual activity is temporarily checked. For example, a man is accustomed to reading the newspaper each evening upon arriving home from work. The situation of arriving at his home builds up a bodily tension of expectancy which leads him to get the paper from the front yard. Let us suppose that one day the paper is missing. The man now searches the yard. Failing to find the paper, he attempts to borrow one from his neighbor or he walks to the corner store to purchase a copy or he hails a newsboy. The persistent tension aroused by the situation motivates a variety of activities until finally one of them is successful in removing the tension.

Thus, it is our view that pure neural readiness exists and that it is not motivating, that this neural readiness determines the pattern of muscular tension aroused by external and internal stimulations, and that the muscular tension (through stimulation of the proprioceptors) is an important source of motivation. The stimulations from the goal-set or the task-set or the situation-set is a definite motivation which is different from that considered in the discussion of the biological drives.

Muscular tension and behavior. The work of G. L. Freeman (8) and others has shown that every individual has a characteristic level of muscular tension. The level of tension varies

with age, metabolic rate, the amount and degree of external stimulation, postural set, frustration, and other factors. The level of tension can be raised by stimulating the organism with lights or sounds or contacts; it can be lowered by reducing these stimulations.

The level of postural tension has an important relation to the efficiency of human performance. Every skilled act has its optimal level of tension. The optimal can be defined in terms of the quantity and quality of work produced. If the postural tension exceeds the critical level for a given task, there is a lowering of the efficiency of work. If the level of tension is very high, a skilled act may be completely disrupted.

There is little doubt that motivation can be regarded as a *quantitative* variable. It varies in degree. One can speak of under-motivation, optimal motivation, over-motivation. The optimal degree of motivation varies with the difficulty of the task, with the skill, precision and co-ordination of movement involved.

Physical and chemical determinants. When behavior is viewed as a physical process the factors which motivate activity must also be regarded as physical in nature. From the point of view of physical science the problem of motivation is to describe how the energy which underlies behavior is released and directed. Viewed in this light, every stimulus which arouses a response is motivating.

Stimuli which release energy and thus motivate behavior are of different kinds: mechanical, electrical, chemical. They are organized into an infinite variety of patterns in space and time. The stimuli which motivate behavior originate in different places: at the surface of the body from the external environment, in the proprioceptors, in the smooth muscles. Despite all of this variety in the stimuli the energy which is manifest either as behavior or as heat is of one kind: physical energy.

The expenditure of energy underlies all of the work accomplished by the human organism. Incidentally, the energy cost of this work can be measured. The stored-up energies of an organism are expended in one kind of activity or another according to the habit-organizations, attitudes, and purposive determinations which are present. What Freud called *sublimation* can be re-described as the re-orientation of the individual so that energy will be expended in one kind of activity rather than another.

The chemical determinants of behavior are of two main kinds. First, there are the external chemical stimuli which motivate behavior as do all other external stimuli by acting upon the receptors. The main chemoreceptors are on the tongue or in the nose. Second, there are internal chemical factors which act upon receptors or nerve cells. They may either excite behavior directly or predispose the organism for a particular kind of response.

There is evidence that the internal chemical state of the rat regulates to some extent his selection of foods. Richter has shown in self-selection feeding experiments that rats are able, within limits, to select and balance a diet according to their metabolic needs. He has produced evidence to show that when a specific substance is needed to maintain homeostasis the taste buds become more sensitive to the presence of that substance.

Again, in the sphere of sexual behavior it is known that the gonadal hormones regulate not only bodily growth but also the patterns of sexual behavior. For example, if the testes and ovaries of chicks are transplanted, the animals bearing the testes (regardless of their original sex) develop the physical characteristics of the male and the masculine patterns of behavior; the animals bearing the ovaries develop the female form and feminine behavior. The gonadal hormones are more important determinants of sexual behavior than any assumed difference between the sexes in neural structure.

Chemical motivation is of basic importance. From the genetic point of view there is some evidence to indicate that it develops prior to motivation through external stimulation of the receptors. Coghill (6) has shown that rhythmic contractions in the embryo toadfish can be accelerated by an increase in the concentration of carbon dioxide in the environment before any response can be evoked through the receptors. The behavioral change is produced by direct internal chemical action.

Psychological hedonism. After considering the physical and chemical determinants of behavior we must make a big jump in turning to the subjective aspect of experience. The entire subjective aspect—including conscious purposes, desires, feelings—cannot be considered for want of space. But brief consideration is given to the ancient doctrine of psychological hedonism.

In its simplest form the doctrine of psycho-

logical hedonism is the proposition that subjectively pleasing activities tend to maintain themselves and to be repeated; subjectively unpleasant activities tend to be avoided and eliminated from behavior.

Hedonistic psychology is implied in the law of effect. In Thorndike's first statement satisfying activities were said to be "stamped in" and annoying activities to be "stamped out." There was the same implication in the older pleasure-pain theory of learning. Hedonistic psychology is implied, also, in the modern analysis of interests and aversions as well as in the current analyses of happiness in relation to marital or other adjustment.

Although interests and aversions can be described objectively in terms of acceptance-rejection or continuance-avoidance of an activity, the fact remains that for most persons an interest is an activity which is subjectively pleasing and an aversion one which is displeasing.

Troland (24) admits pleasantness and unpleasantness as primary subjective data. He states that the problem of motivation is a psychophysiological one. After analyzing hedonistic theories of motivation and classifying them as hedonisms of the past, the present, and the future, Troland accepted a hedonism of the past. By this he meant that previous experiences of pleasantness and unpleasantness were actual factors in determining an individual's psychological structure; hence they regulate contemporary behavior. The theory has not won wide acceptance probably because subjective psychology has been under suspicion.

Holt (10) has faced the problem from an objective point of view. He coined the terms *adience* and *abience* to designate the reactions of acceptance and rejection. There is no doubt that adient and abient behavior can be analyzed objectively and in a quantitative manner. The conditions which determine it can be studied. But at the present time we do not know why some activities are adient and others abient.

A great many human activities have no apparent biological utility. They are said to be carried on just for fun, for the enjoyment they bring. A business man carries on his hobby—golf, hunting, stamp collecting—just for fun and relaxation. An artist enjoys colors and forms even when there is little meaning to the product of his art. A child plays, observes, explores, manipulates, vocalizes—just for fun.

The attempt to show that all of these activities are supported by the primary biological drives is futile and misguided. A good many psychologists, however, hesitate to admit that pleasant and unpleasant feelings motivate behavior. The difficulty can be stated in this manner: Behavior can be described as physical movement. The motivation of behavior, from first to last, is a physical process. Pleasantness and unpleasantness are subjective data. By definition they are mental, not physical. Hence, these feelings cannot motivate human behavior.

The argument implies a misconception. The facts of human experience, whether reported from a subjective or an objective point of view, are the ultimate data upon which analysis of human motivation must rest. Pleasant and unpleasant experiences, directly reported, are among the *givens* to be explained. Ultimate explanation in psychology must take account of all the facts, including subjective data.

As a temporary expedient the present writer suggested a doctrine of *factual hedonism*. This is not a theory of motivation. It is merely a frank recognition that pleasant feeling *as a fact* is associated with activities that tend to continue and be repeated as well as with the relief which comes with success and the making of a goal-response; and that unpleasant feeling *as a fact* is associated with activities that tend to be avoided as well as with frustrations, conflicts, and failures. Factual hedonism leaves open the door to further investigation.

Dynamic psychology. The history of psychology is replete with hypothetical systems for explaining human behavior in terms of instincts, propensities, wishes, wants, desires, needs, forces, and tensions. These systems differ widely from each other; scarcely two of them agree. A recent example is the system of Murray (17). He has worked out an elaborate system of human needs. The primary needs are viscerogenic; they are the same as the commonly recognized biological drives. The secondary needs are psychogenic; of these Murray lists twenty-eight, including such needs as acquisition, construction, dominance, blame-avoidance, and play.

Lewin (14) has assumed internal motivating tensions which have their outer counterpart in positive and negative behavior. The objects in an individual's environment are said to have positive or negative valence according to whether

the individual behaves positively or negatively with respect to them. Lewin has drawn an important distinction between manifest behavior and underlying motivation. Two patterns of behavior may be similar in form (phenotypically similar) but different in motivation: A friendly manner may conceal the determination to carry out an aggressive act or to destroy; the overt behavior resembles that of a true friend but the motivation is different. Again, two patterns of behavior may be different in form but similar in motivation (genotypically similar): A man under tension to mail a letter may relax this tension by handling the letter to a postman, putting it in a letter box, or asking a friend to mail it.

The work of Lewin has a definite relation to the dynamic psychology which has developed largely through the influence of psychoanalysis. Space does not permit an elaboration in this area but the following terms are listed merely to suggest important dynamic principles: *identification, projection, rationalization, compensation, repression, regression, substitution, self-defense, frustration-aggression, dissociation*. These terms suggest a dynamics of human behavior of which the individual, to a considerable extent, is not conscious.

In this connection a final word may be added about psychosomatic medicine, a contemporary development within dynamic psychology. The emphasis in psychosomatic medicine is upon the individual as a whole. He is regarded as a unit and not a mind plus a body. From this point of view it is clear that frustrations and conflicts may have physical symptoms and that attitudes and motives may effect both behavior and conscious experience.

The present writer believes that a monistic psychology such as that we find in psychosomatic medicine is required to bring together into a single theory of motivation the diverse facts and principles briefly outlined above.

For further study of motivation see the articles on attitude, emotion, experimental psychoanalysis, experimental psychopathology, frustration-aggression hypothesis, interest, and work. For general orientation see *Motivation of Behavior* by Young (28) and the article, entitled *Motivation*, in *Monroe's Encyclopedia of educational research* (29).

MULTIPLE FACTOR ANALYSIS.—

This is a technique for determining, by the statistical analysis of a set of intercorrelations among a number of tests, whether a few elements run as common factors through all the tests; and, if there are such common factors, with what weight each of the tests is loaded with each of the factors. For example, the "intelligence" measured by the so-called intelligence tests may be a combination of more fundamental abilities such as the ability to generalize inductively, to interpret verbal symbols, to work with numerical concepts, etc. The several available instruments may test these different components to varying extents. By bringing together measurements from a number of such tests by means of the coefficients of correlation between them, and suitably analyzing this set of intercorrelations, it is possible to determine how many factors, if any, are common to the tests, and to what extent each test is potent for measuring each of the common factors (that is, is "loaded" or "saturated" with each factor). Charles E. Spearman opened this sort of inquiry in England near the beginning of the present century, taking the intercorrelations in com-

binations of four by the so-called "tetrad difference method," in which he tested the hypothesis that only one factor might be common to all the tests. In present practice all the intercorrelations are investigated together and the hypothesis of either one or more common factors is investigated simultaneously.

It is customary to carry the treatment of this topic in terms of the geometry of n -dimensional space. But in this article we shall first give an exposition of the technique in analytic terms only (that is, algebraic terms), because that form is much simpler for the reader who is untrained mathematically. Thereafter we shall relate this approach to the conventional geometrical one.

II

Probably all, or nearly all, human abilities rest upon a number of constituent elements or "determiners." The same thing is true of all sorts of traits, whether dynamic psychological characteristics of persons, or tendencies toward certain entelechies or responses on the part of plants or animals, or the operation of social institutions. Where learning is possible, as it is where individual or social human or animal behaviors are involved, these elements tend, as the learning proceeds, to get integrated into consistent patterns which express themselves in techniques of behavior. If some of the same elements enter as components in each of two performances (when we use this term to include the attainment of physical characteristics as well as the expression of human or animal abilities), measures of the two performances in a set of subjects will be correlated in the technical sense of that term, the coefficient of correlation expressing the degree of overlap by reason of the common elements (7, pp. 120-123). For the sake of simplicity of language we shall henceforth call any instrument for measuring performance a "test," and the number of units of a variate that any individual is found to exhibit when measured by a test we shall call his (or its) test score. We can determine whether there is an element common to two traits (or a set of common elements cohering consistently through our sample) by ascertaining whether there is a coefficient of correlation that departs from zero between the scores on these traits when each of N individuals is tested in both of the traits. Conversely, if the two

tests are correlated by an amount that differs from zero, that fact gives evidence of an element, or a coherent set of elements, common to the two.

When we have a set of intercorrelations differing from zero from a plurality of tests, they give evidence that the measured traits overlap. But we do not know by direct inspection whether the elements that produce the correlations are common to all of the traits or whether different elements are common to the different pairs. There are four possibilities:

1. Each correlation coefficient may be due to an element common to only its pair of traits.
2. One common element may run through all of the traits.
3. Certain elements may be common to groups of traits but not to all of them.
4. Possibilities 2 and 3 may both be realized.

It is the purpose of multiple factor analysis to get an answer to the questions posed by these four alternatives. It is, in other words, the object of multiple factor analysis to ascertain how many (usually independent) factors, either common to all of the tests or to groups of them, are needed to explain a set of intercorrelations; and to ascertain the degree to which each of the tests from which the intercorrelations arise is saturated ("loaded") with each of the factors.

Consider a series of tests designated a, b, c, \dots, n respectively. Let their scores be in standard form; that is, $z_1 = x_1 \sigma_1$. And let there be running through the intercorrelations common factors designated by the subscripts 1, 2, 3, \dots, r . If we assume only rectilinear relations (as we must since we are dealing with Pearsonian coefficients of correlation), we can express an individual's total standard score on test a as the sum of his standard scores on the several factors, each weighted by the test's loading in these respective factors:

$$z_a = a_1 z_1 + a_2 z_2 + a_3 z_3 + \dots + a_r z_r \quad (A)$$

Similarly, his standard score in test b is

$$z_b = b_1 z_1 + b_2 z_2 + b_3 z_3 + \dots + b_r z_r \quad (B)$$

In order to simplify the concept and the procedure we set the condition that the factors we are seeking shall be independent (that is, uncorrelated, another term for which is "orthog-

onal"). If, now, equations (A) and (B) are multiplied together, summed for the N individuals of the sample, and divided by N , terms of the form $\sum z_1 z_1 / N$ will equal 1 because each is the variance of a set of standard scores, and those of the form $\sum z_1 z_j / N$ ($i \neq j$) will approach zero because they are the correlation coefficients between the factors which, by hypothesis are all zero; and $\sum z_1 z_{r+1} / N$ is r_{1b} ¹. We shall then have:

$$r_{1b} = a_{1b_1} + a_{1b_2} + a_{1b_3} + \dots + a_{1b_r} \quad (C)$$

By intermultiplying the equations from all the tests we get n^2 equations, one from each of the intercorrelations, $n(n+1)/2$ (including those of the form r_{kklk}) being different from one another as:

$$\begin{aligned} r_{aa} &= a_{1a_1} + a_{2a_2} + a_{3a_3} + \dots + a_{ra_r} + \dots \\ r_{ab} &= a_{1b_1} + a_{2b_2} + a_{3b_3} + \dots + a_{rb_r} \\ r_{ac} &= a_{1c_1} + a_{2c_2} + a_{3c_3} + \dots + a_{rc_r} \\ r_{ak} &= a_{1k_1} + a_{2k_2} + a_{3k_3} + \dots + a_{rk_r} \end{aligned} \quad (D)$$

We may continue to set up corresponding equations for r_{bl} , r_{cl} , etc., where the subscript i stands for each of the tests in turn. These equations must all be true simultaneously. Hence we have the familiar (but often intricate) job of solving a set of simultaneous equations to find the unknowns, a_1 , a_2 , b_1 , b_2 , etc., which are the factor loadings of the several tests.

Two types of methods have been used to solve this set of simultaneous equations.² In the "centroid method," devised by L. L. Thurstone, a solution is sought that will make the *sum of the factor loadings* a maximum. The alternative type of method, popularly known as the Hotelling "Method of Principal Components," but employed even earlier in slightly different forms by Thurstone and by Kelley, maximizes the *sum of the squares* of the loadings. Contrary to the widespread belief that these are basically different, rival methods, the essential difference between the two types of procedure is the simple one just mentioned.

¹ Some factorists sum through the whole population instead of through the sample, in which case $\sum z_1 z_1 / N$ must be replaced by $\sum z_1 z_1$; they must then work in terms of the coefficients of correlation "corrected for attenuation."

² We shall not consider here the tetrad difference method, devised by Spearman, which was historically the precursor of the present multiple factor methods. If the reader is interested, he may look it up in references 5, 7, and 8 listed at the end of this article.

For the solution by first moments (the "centroid" method) we sum the terms in the simultaneous equations by columns. This results in the equation

$$\Sigma r_{1j} = \overline{\Sigma k_1^2} + \overline{\Sigma k_2^2} + \overline{\Sigma k_3^2} + \dots + \overline{\Sigma k_r^2}$$

where Σr_{1j} is the sum of all of the intercorrelations (each entered twice except those of the type r_{11} which enter only once each), Σk_1 is the sum of the first factor loadings in all the tests (which is squared *after* summing), Σk_2 is the sum of the second factor loadings in all of the tests, etc. But this is an indeterminate equation; it contains r sets of unknowns and only one equation. We can solve it only by imposing enough conditions to reduce the number of unknowns to the number of equations. That is, we must impose $(r-1)$ conditions where r is the number of factors. And we must impose such conditions as will make the remaining unknown for which we are seeking a solution a maximum. So we impose provisionally the condition that each of the terms in Σk shall be zero except the first. This automatically maximizes Σk_1 and permits us to get a solution *subject to this condition*—a condition which can later be revoked if we choose. It is not appropriate to give here a detailed account of the method, but the reader can find it explained and illustrated in a number of places (Ref. 2; 7; 9, ch. II; and 10, ch. III, and Appendix 1). After provisional loadings have been found for the first factor, a table of residual correlation coefficients is determined and, by imposing $(r-2)$ conditions like those for the first factor, a set of provisional loadings is found for the second factor. The solution continues in this manner until all significant factors have been isolated.

The "principal components" (Hotelling) method seeks a solution that makes the sum of the squares of the factor loadings a maximum. For this purpose an expression for the sum of the squares of the loadings is set up and partial derivatives of it are taken and each partial derivative equated to zero. This yields $(n+1)$ equations where n is the number of tests and also the number of factors, so that there are as many equations as unknowns. Hence the set of simultaneous equations is capable of a unique (that is, a single) solution. But when the determinant is evaluated in which the coefficients in the equations are set up for solution it yields a

"characteristic equation" of the n th degree; that is, with exponents running up as high as n . No general method is available for solving an equation of high degree; such equations must be solved by approximation methods. One resort is, therefore, to variations on a scheme of guessed multipliers devised by Sir Isaac Newton some 250 years ago which causes the trial roots to converge rather rapidly to a close approximation to the true ones. Hotelling devised an ingenious method of this type which permits approximation to the roots by a series of multipliers applied directly to the coefficients of the correlation matrix. This is the so-called "iterative" method. In this manner the largest root of the characteristic equation is obtained to a close approximation.

After the first factor loadings have been thus determined, tables of residual correlation coefficients are derived just as in the centroid method, and subsequent factors are isolated by the same technique as that employed for the first one.

Both methods give usually all positive loadings in the first factor and, in each of the subsequent factors, about as many negative as positive loadings. In fact, the matrix of factorial loadings before transformation (a term to be explained in the paragraph third below this one) are very closely alike from the two methods, particularly the first several factors. Table I gives the factorial matrix (table of factor loadings) before transformation from a problem devised by the author of this article to illustrate, and test the validity of, the process of multiple

factor analysis. These loadings were obtained by the centroid method. The values in parentheses are the known true values. These loadings for the first factor correlated .998 with the ones obtained by the Hotelling method for the same factor, although the mean loading by the Principal Components Method was a little larger than that by the Centroid Method. This particular coefficient of correlation was somewhat higher than would usually be obtained, but the agreement is regularly very close; and it is also a regular finding that the amount taken out in the early factor loadings is slightly greater by the Principal Components Method than by the Centroid Method.

We return now to the stage where, in the Centroid Method, we provisionally imposed sufficient conditions upon our otherwise indeterminate equation to permit us to get a solution. In the equation

$$\Sigma r_{1j} = \overline{E_k}^2 + \overline{E_{k_2}}^2 + \overline{E_{k_3}}^2 + \dots \overline{E_{k_p}}^2$$

we imposed the condition that $\overline{\Sigma k_2}^2 + \overline{\Sigma k_3}^2 + \dots \overline{\Sigma k_p}^2$ should be zero. That enabled us to get a solution, but it had the effect of throwing back into the sum of the first factor loadings all the excess of positive loading above zero from all of the remaining factors. Hence the first factor loadings as they stand after this provisional solution contain, in a sense, all the others.

That this is true is indicated by the analytic consideration mentioned above, and is further evident from consideration of what is indicated in the geometrical picture of passing the first axis through the centroid of the system. But this interpretation is also subject to verification by empirical test. The author of this article set up a matrix of intercorrelations based on penny tossing in a manner that would precisely simulate the conditions to which factor analysis methods are applied, with known factor loadings, and then factored the matrix, the results being those shown in Table I. If the above hypothesis is correct, that the first factor includes all of the succeeding ones, and each next factor includes all that follow it, the first factor should, before this combination of elements is separated by transformation, correlate low with the corresponding known weightings because the correlation coefficient turns on the per cent of elements that the two correlated arrays have

TABLE I
A MATRIX OF FACTOR LOADINGS
BEFORE TRANSFORMATION
(Known true factor loadings in parentheses)

Test	Factors			
	1	2	3	h
a	+ .842(.8)	-.359(.3)	+.079(.1)	.844(.74)
b	+.517(.7)	-.373(.0)	-.124(.1)	.422(.50)
c	+.612(.3)	+.027(.3)	+.043(.3)	.377(.27)
d	+.719(.3)	+.261(.4)	-.237(.6)	.641(.61)
e	+.702(.5)	+.103(.4)	-.233(.3)	.558(.50)
f	+.790(.6)	+.063(.3)	-.244(.5)	.688(.70)
g	+.863(.7)	-.248(.4)	+.050(.3)	.809(.74)
h	+.882(.7)	+.142(.5)	+.067(.3)	.803(.83)
i	+.623(.4)	+.086(.5)	+.267(.0)	.467(.41)
j	+.481(.2)	+.213(.6)	+.314(.0)	.375(.40)

in common, which per cent would be low if extraneous other elements were present and high to the extent that the impure array was purified by the separation out of these extraneous elements. Each succeeding column of factor loadings should correlate more highly with the true loadings because each has extraneous to itself only those beyond it. The coefficients of correlation between the untransformed loadings of Table I from our trial problem and the corresponding true ones behaved in precise conformity with that hypothesis: in factor 1 the r was .63; in factor 2, .70; and in factor 3, .78.

So in order to untangle the factors which are embedded together in the first one, and to a decreasing extent in each succeeding one, the provisional condition originally imposed is lifted and alternative conditions are imposed. The loadings in the factorial matrix are interrelated in the form:

$$\begin{aligned} a_1b_1 + a_2b_2 + a_3b_3 + \dots &= k_1 \\ a_1c_1 + a_2c_2 + a_3c_3 + \dots &= k_2 \\ b_1c_1 + b_2c_2 + b_3c_3 + \dots &= k_3 \end{aligned} \quad (E)$$

where the k 's are constants. Since the values for a_1 , b_1 , etc., are all provisional, determined merely by the condition imposed to get the tentative solution, any other value that serves our purpose may be substituted for any one of them, whereupon all of the others in the interdependent system will need to take on changed values so as to keep the system of equations consistent. Thus the system can be put through a transformation into another which completely satisfies all of its fixed conditions. The transformation must involve at least two columns of the factorial matrix but it need not extend beyond two at a time. But whenever a new value is substituted for any one of the test loadings within the two columns involved in the transformation at any one time, all of the others must follow along as dependents, since the elements are all interrelated. Simple equations for effecting these transformations are available (7, p. 266). The transformations are usually carried along by pairs of columns (although they can all be carried simultaneously [11]) until a satisfactorily meaningful form is attained, out of the infinite number of different forms that would be possible.

If it were only possible to know the true factor loadings of one of the tests, the worker could make these known loadings the point of

departure and obtain a unique solution. In the absence of any such guidance, the resort must be to certain criteria of plausibility and usefulness. It is not plausible that loadings should extend below zero because such a fact would mean that the possession of the "ability" measured by the test is a handicap to the subject. So one useful criterion is to raise the factor loadings so that they will all be positive (except for the possibility of a few small negative ones which can be charged to errors of sampling). In Table I this may be achieved in respect to column 2 by setting its lowest loading ($-.373$ for test b) equal to zero and effecting the consequent transformation by the formulae of reference 7 mentioned above. Then other transformations can be made until the "positive manifold" shown in Table II is attained.

TABLE II
MATRIX OF FACTOR LOADINGS AFTER
TRANSFORMATION
(Known true factor loadings in parentheses)

Test	Factors			h^2
	1	2	3	
a	+ .744(.8)	+ .201(.3)	+ .501(.1)	.845(.74)
b	+ .619(.7)	.0 (.0)	+ .200(.1)	.423(.50)
c	+ .401(.3)	+ .380(.3)	+ .270(.3)	.378(.27)
d	+ .491(.3)	+ .632(.4)	.0 (.6)	.641(.61)
e	+ .558(.5)	+ .494(.4)	+ .042(.3)	.557(.50)
f	+ .647(.6)	+ .513(.3)	+ .078(.5)	.688(.70)
g	+ .716(.7)	+ .303(.4)	+ .452(.3)	.809(.74)
h	+ .521(.7)	+ .631(.5)	+ .364(.3)	.802(.83)
i	+ .270(.4)	+ .434(.5)	+ .454(.0)	.467(.41)
j	+ .080(.2)	+ .454(.6)	+ .403(.0)	.375(.40)

The three factors in this particular problem have now been untangled; they are comparable with one another in a meaningful way, and they are now in close agreement with the known true weightings. They now correlate with the known loadings as follows: factor 1, $+.84$; factor 2, $+.73$; factor 3, $-.72$.

It has not been customary to transform the system of factor loadings obtained by the Method of Principal Components, because, having been obtained by the method of least squares, the first solution is unique. It is said that, if they were transformed, they would no longer be the principal components (9, p. 78)—that is, projections on the principal axis of an ellipsoid.

But, as both their close agreement with the factors obtained by the Centroid Method would suggest, and as consideration of the image of ellipsoids of equal density in n -dimensional space would reveal, each earlier one in the series does contain enmeshed within itself all that follow, just as in the Centroid Method; and they need to be untangled if they are to be maximally meaningful. There results from the Principal Components solution the same type of system of interdependent equations as shown at (E) above, although the particular values are a trifle different from those by the Centroid Method. From the analytic standpoint this system of interdependent equations can be put through transformations as legitimately as those from the Centroid Method. If the geometrical picture as ellipsoids of equal density does not lend itself as well to this as Thurstone's geometrical picture of an r -dimensional spheroid, that seems to indicate a certain infelicity in the geometrical representation rather than a reason why the transformation should not be carried through analytically.

III

If the reader of this article has had any previous contact with the literature on multiple factor analysis, he will not recognize the above account. That is because our account has been carried wholly in analytic (that is, algebraic) terminology, while the conventional treatments of this subject have nearly all been in terms of the geometry of n -dimensional space. As a matter of fact, practically every argument in mathematics can be carried in either analytic or geometrical form, or by an interplay between these forms, with identical outcomes and with identical meaning. Indeed, in the original articles on multiple factor analysis the basic derivations are usually carried analytically and are then translated into geometrical pictures that they "may be regarded as." There is no ramification of this subject that has a mathematical basis which cannot be developed and expressed analytically, just as there is also no ramification of it which cannot be conceived in geometric imagery. And the same is true of mathematical arguments with other types of subject matter. For example, if we have an equation in x of degree n and can know, by solution or by assumption, one root, a , then the equation can be divided by $(x-a)$, whereby its highest expo-

nent is reduced to $(n-1)$. This equation can be conceived as plotted in space of n dimensions and a plane representing the condition $x = a$ can be passed through the configuration, whereupon the resulting hyperplane has its dimensionality reduced to $(n-1)$. A correlation coefficient, which is analytically expressed by $\Sigma xy / N \sigma_x \sigma_y$, can also be put as the cosine of an angle between vectors in space of N dimensions where N is the number of pairs of subjects tested. Where n is the number of tests, correlated tests as wholes can be posited in an n -dimensional spheroid in positions determined by vectors which connect them with the center of the system and which have their directions determined by the fact that the cosines of the angles between pairs of them equal the inter-correlations; or they can equally legitimately be represented by a matrix of intercorrelations in arithmetic form. Parallelism between the analytic procedure and the geometrical may be well illustrated by the process of transforming factor loadings. As said above, we have in the factorial matrix expressions of the type

$$a_{11}x_1 + a_{12}x_2 = k_1$$

which we may analytically transform to

$$a_1'b_1' + a_2'b_2' = k_1$$

But any expression of this form, no matter what the nature of the subject matter so long as each of the elements lies between plus and minus 1 and k_1 and k_2 is a constant, can be put into trigonometric form. For if $a_1 = \cos x$, $b_1 = \cos y$, $a_2 = \sin x$ and $b_2 = \sin y$, the expression becomes that for the cosine of the difference between angles x and y . So whenever one of the elements, say $\cos x$, is set to conform to an imposed condition, all the other three dependent ones are determined. So the transformation can always be represented in space and performed by the manipulation of angles between the fixed vectors and the movable axes as a process of rotation just as feasibly as it can be handled by algebraic means, and with identical outcomes. Here x and y are the angles made respectively by the two test vectors with the axis, while $(x-y)$ is the angle between the vectors, which is constant whatever the position of the axes.

When the process of transformation of factor loadings is carried in geometrical form as a process of rotation, the ideal to be achieved by

FIGURE 1. Factor loadings for columns 1 and 2 plotted. Solid lines are axes before rotation; broken lines, after.

the rotation is expressed in two optima: (1) a positive manifold; (2) simple structure. For two factors the geometrical picture can be drawn on plane paper with two perpendicular lines representing the orthogonal axes. The first of these optima would be fulfilled if the axes could be so rotated that none of the tests would fall outside of the quadrant AOB; the second, if most tests fell on the boundary lines rather than somewhere within the quadrant.

For three factors the representation must be on a sphere, with the tests projected to the surface by "correction for uniqueness." If there is a positive manifold, none of the points representing the tests will fall outside of a spherical triangle (a right spherical triangle if the factors are "orthogonal"); if there is simple structure, they will fall on the sides of this spherical triangle rather than within it. The intersections of the hyperplanes passing through the vectors of the tests which lie along the arcs in simple structure determine the "primary trait" vectors; to the extent to which tests lie not only along

the sides of the triangle but near the vertices, to that extent these tests are relatively pure measures of the "primary abilities." An analogous arrangement holds as we pursue the case of four or more factors into space of four or more dimensions. All of these criteria have their exact counterpart in analytic form; and the extent of attainment of each can be observed by merely inspecting the transformed factorial matrix. We have a positive manifold if all of the loadings in all of the columns have the positive sign, or if the negative values are so small that they can be attributed to errors of sampling; we have simple structure if in each row there is at least one zero and preferably more; and we have relatively pure tests of primary abilities if, in the several columns, the loadings are heavily concentrated in one, or a few, tests while the other tests in their respective rows have zero or low loadings. These simple relations hold for the case of independent factors; when (and if) the transformations are not orthogonal, the matter becomes much more complicated.

IV

The Chicago school in particular has held high hopes that we could find primary abilities by the optimum selection of tests and the optimum rotation of axes. This hope is predicated on the belief that there are real independent abilities rather than mathematical artifacts which multiple factor analysis can isolate. This has led them not only to search diligently for just the right position of the axes, so that the traits could be identified as familiar ones, but also to the expedient of "oblique axes." That is, if the geometrical picture reveals that we might get more nearly simple structure by letting our axes sag away from perpendicularity (that is, by not imposing the assumption of independence of the factors), we may do so and determine our loadings with the admission of some correlation among them. In fact, this is the general case. Multiple factor analysis does not necessarily assume that the primary factors are uncorrelated in the general population, although it usually (though not necessarily) sets up an orthogonal reference frame for simplicity in solving the fundamental equations to get the original arbitrary loadings. From those orthogonal reference frames the members of the Thurstone school rotate the axes into any positions which seem best to identify the primary abilities they are seeking, including positions in which the axes are related by oblique rather than right angles.

But time may well prove that the hope of finding many important primary abilities, fundamental and invariant from test battery to test battery, is a vain one. We can, however, fix certain "cores" which are uncorrelated and which can be used conceptually to describe a complex of behavior as exhibited in a set of tests. In most cases we may not be able to name these perfectly by any of our conventional labels. For any name that we can use will include more than the factor, since practically any trait of which we know the name in life is a compound of "a man's successive performances or behavior as integrated throughout the duration of his life" (1, p. 237); and also one which is likely to center in its connotation somewhat off of the point isolated by our mathematical processes. A corresponding difficulty, plus some serious additional ones, will be encountered when we attempt to make pure tests for measur-

ing the isolated abilities. MacKinnon (4, p. 35) has expressed this point of view as follows:

The more scientifically sophisticated factorists think of factors as *systems of coordinates*, as simple and parsimonious frames of reference for the classification and interpretation of the underlying variables of personality. For them, factors are not faculties or traits existent in concrete personalities, but rather convenient descriptive categories which enable the factorist to generalize and simplify test results and make predictions about people with a maximum degree of efficiency. (See also Ref. 1, p. 237.)

The most extensive application of multiple factor analysis has been to the analysis of psychological tests. But it can also be applied to the analysis of persons (1, ch. 6), and each person's ability in each of the isolated factors can be expressed in an equation and calculated. The technique has been applied to the analysis of newspapers and could be applied to many other sociological data. It should also be applicable to problems of production and of growth in agriculture and to problems of nutrition and health of human beings as well as to other medical problems. But it must not be supposed that it can replace the older technique of multiple regression where prediction of a criterion, and the analysis of the components of a team of factors in relation to a criterion, are at stake. Multiple factor analysis is useful where a plurality of measurements suggests a functional unity but in which there is reason to suspect more elementary components, and it is desired to ascertain how many such components are required to account for the intercorrelations resulting from the measurements and to study the nature of these components. Multiple regression is useful where it is desired to predict a criterion with maximum effectiveness and to study the net weight of each of the constituent elements in the team for predicting the criterion.

NATIONAL COUNCIL OF WOMEN PSYCHOLOGISTS, THE.—During the fall of 1941, a group of New York City women psychologists met several times to discuss the feasibility of a national organization of women psychologists to participate actively in the nation's emergency and war effort. Already during annual meetings of the national psychological associations, when the rumblings of war were first audible, women had considered phases of such participation, as it seemed that even though specialists they would not be included in the various types of psychological work in connection with selection and placement in the armed forces of the country—perhaps of necessity then. However, since there were undoubtedly many types of professional services to the community in wartime which women psychologists might undertake, and ways of serving their country professionally, a steering committee was formed at a meeting in New York City in December, 1941, to proceed with the details of a national organization.

All women psychologists in this country who were qualified for membership in such an organization under the terms of a constitution drawn up by the Constitutional Committee, of which Dr. Ella Woodyard was chairman and Drs. Alice Bryan and Gladys Schwesinger members, were invited to become charter fellows of the National Council of Women Psychologists. Within the prescribed time 234 women, fulfilling the requirements, including the Ph.D. degree in psychology, had accepted this invitation. A slate of officers prepared by a Nominations Committee consisting of Dr. Clairette P. Armstrong, chairman, with Drs. Helen Richardson and Mildred Mitchell members, was sent to each fellow to be voted on, together with the proposed constitution. By June, 1942, the National Council of Women Psychologists was functioning widely under Dr. Florence Goodenough, president; Dr. Helen Peak, vice-president; Dr. Theodora M. Abel, treasurer; Dr. Gladys Schwesinger, secretary, and eight board members, Drs. Marion Bills, Alice Bryan, Ed-

wina Cowan, Florence Mateer, Myrtle McGraw, Harriet O'Shea, Ruth Tolman and Dorothy Van Alstyne. There were 261 members by January, 1943.

The NCWP constitution and by-laws were adopted by more than 80 per cent of the members except for one clause which referred to disbanding after the war. Some thought such an organization could be useful in peacetime or that the post-war situation should guide future action, although the stated aim, namely of developing the services which properly trained women psychologists can perform in community and nation in time of war, stood approved.

At the first NCWP board meeting held by Dr. Goodenough in New York City July 29, 1942, representatives of three local units were present and petitioned for recognition. Such units were provided for by the constitution, to be subsidiary to the national body and operative under its laws. At this time were chartered the New York Unit, Rockland County (New York) Unit, and the Philadelphia Unit. A little later the Boston Unit was also affiliated. Local units planned to cooperate with the volunteer war emergency organizations offering assistance as psychologists. Each unit also held a number of meetings at which reports were given by psychologists of their activities in the various emergency organizations and plans for greater usefulness laid.

The largest unit, numbering fifty-one, in New York City, presided over by Drs. Armstrong, president; Barbara Burks, vice-president; Cecile Flemming, secretary-treasurer, and Alice Bryan, Emily Burr, Gladys Schwesinger and Ella Woodyard, board members, voted to admit to memberships auxiliaries with lower qualifications than the regular members, to work under their direction and assist on various projects. The New York Unit, having offered its services to the Civilian Defense Volunteer Office, was busy with plans to meet emergencies which might arise, especially if the war were carried to these shores. Dr. Myrtle Pignatelli was appointed representative to serve as a member of the CDVO

Advisory Committee on the Training of Volunteer Workers, which held monthly meetings at City Hall. In the days when warnings of bombings were frequently reiterated by officials, the Department of Training of the CDVO expressed appreciation of the professional services of the New York Unit, and some members were allocated as consultants to the different boroughs of New York to deal with special problems requiring psychological guidance.

The Rockland County Unit under Drs. Elaine Kinder, president, and Margaret Mercer, secretary-treasurer, soon decided that in view of their small number it would be more expedient to dissolve and join forces with the New York group.

The Philadelphia Unit, presided over by Dr. Mildred Sylvester, with Dr. Selinder McCaulley, secretary, carried on a great deal of volunteer work predominantly in connection with the enrollment of the WACs.

The Boston Unit, led by Drs. Marie Rickers-Ovsiankina and Rosaline Goldman, secretary, appointed upon request special members for special jobs, such as interviewing WACs. There were also two active committees, one dealing with marriage counselling—war marriages and difficulties of the returning veterans and their families, the other with combating intolerance in children.

An NCWP Committee on Publications, synchronous with its beginnings, under the co-chairmanship of Drs. Dorothy Nyswander and Kathryn Maxfield, sponsored outlines for discussion groups and courses contributed by members, to assist in solving community problems. These outlines, though only mimeographed, were ordered widely. There has been an especially large circulation of Dr. Harriet Fjeld's "Training Leaders of Discussion Groups," which was used by such groups as the Boy and Girl Scouts, the Y's, etc. Dr. Ruth Valentine's "Problems of Youth," Dr. Ruth Strang's "Meeting Emotional Strain in School Teachers," as well as Dr. Roberta Crutch's "Teaching Babies to Eat: War Time Conditions," and "The Challenge of the War to Rural Citizenship," by Dr. Lillian Portenier; illustrate the diversity of topics. The outline of a course of six sessions on Psychological First Aid, devised by Dr. Jeanne Gilbert with the collaboration of Dr. Armstrong, was used for many classes of housewives by the former under the auspices of the Ameri-

can Women's Voluntary Services in Brooklyn, and by the latter for other groups in New York City.

Dr. Georgene Seward's Committee on Post-war Planning for Women carried on research, published findings and finally affiliated with the SPSSI Committee on Roles of Men and Women in Post-war Society.

NCWP has received requests from other associations, often women in other professions, for cooperation in their activities. Also inter-professional matters have claimed attention. The Emergency Committee in Psychology of the National Research Council in 1943 invited NCWP to elect a representative to this committee, and the board appointed Dr. Bryan, who recently reported that much of the work of the committee is still bound by wartime secrecy and will not be released publicly until after the war. Two delegates, Drs. Goodenough and Schweisinger, with Drs. Abel and Bills as alternates, were elected in 1943 to serve on the Inter-Society Constitutional Convention engaged in reorganizing the APA.

Because of the war emergency restriction on convention travel, the NCWP annual business meetings have usually had to be omitted and affairs conducted largely by mail. Regional meetings have been held by members residing in the environs, coincident with skeleton meetings of other psychological societies. In September, 1944, the vice-president, Dr. Grace Arthur, presided over an NCWP session to discuss various questions, at the time of the APA Cleveland meeting. In April, 1945, after the EPA meeting, President Armstrong conducted a business meeting at Columbia University, following a luncheon program at which Dr. Bills discussed "Psychologists as Personnel Directors in Industry"; Dr. Frances Triggs, "The Psychologist's Contribution to the Field of Nursing," and Lieutenant Mildred Mitchell described her work as psychologist in the Navy.

With the cessation of hostilities on the European front, the Philadelphia and Boston Units have disbanded. The New York Unit, guided by President Burr, has various projects on hand, particularly in connection with returning service women. The National still stands ready to render any assistance possible.

CLAIRETTE P. ARMSTRONG,
President, 1944-1945

NATIONALISM.—Nationalism is one of the most vigorously dynamic attitude patterns prevalent in the world today, being comparable in potency to the religious fervor of the Crusades. By virtue of its affinity for aggressive impulses, it is a powerful factor in modern wars (cf. War and Peace).

The extent to which nationalism is a generalized attitude pattern has been demonstrated by various investigators, e.g., Ferguson (2), Stagner (12), Murphy and Likert (10). In the United States it involves a considerable number of superficially unrelated elements, such as support of protective tariff and big armaments, hostility to communism, and defense of national honor. It would probably be misleading, however, to emphasize specific issues. At one time the nationalist may be found engaging in imperialist expansion, whereas at another stage in history he will favor encapsulated isolationism. The Russian nationalist obviously approves of communism, while the German Nazi abhors it. The one point which all nationalists have in common is a focusing of attention, drive and positive emotion on the symbols of the nation.

Characteristically, modern nationalism is featured by the delusions of national virtue, national grandeur and national persecution (Stratton, 14). Thus the German nationalist believes that his Fatherland has always played a cultured, progressive role in international relations, whereas persons holding other symbols dear have quite an opposite view. The German has delusions of grandeur, which often take the form of yearning for world domination; Britons and Americans prefer to daydream of prestige and power for their respective countries. The Nazi experiences delusions of persecution, which have an extraordinarily wide scope, including persecution of his mother country by Jews, Communists, Britons, and Frenchmen, among others from time to time. Most nationalists have their persecutory reactions, although these are most virulent in aggressive nations, formerly those known as the Axis.

These elements of the nationalist pattern are referred to as delusions because they are characteristically irrational. Like the delusions of the neurotic and psychotic, they ignore realities conflicting with the major tendency; facts are distorted and meanings twisted to support the nationalist thesis; positive fabrications occur in

the literature of all nationalisms, devised either cynically for the entrapment of the gullible, or unconsciously under the pressure of strong motivation.

The crucial questions, from the psychological point of view, regarding nationalism are: What are the dynamic factors which give it such extreme power in controlling behavior? What are the environmental factors which channel these emotional and motivational elements into the nationalist pattern?

Regarding the first of these, opinion seems agreed that two major considerations are involved: transfer of emotional value from parents to national symbols; and displacement of drives from personal to group goals.

It is intrinsically easier to demonstrate the relation of nationalism to parent attitudes than to demonstrate displacement of drives. The universal use of phrases such as "Fatherland" and "mother country" is an obvious cue. Psychoanalytic-minded investigators, such as Fairbairn (1), Hopkins (3) and Lasswell (7), have reported numerous instances of dreams and free association material revealing the intimate relationship in the minds of their subjects between parent and national symbols. From such clues we are led naturally to the child's delusions regarding the virtues and potency of his parents, which seem to furnish the prototypes for corresponding delusions relative to the nation.

In addition to this material of a qualitative nature, we find some recent statistical studies which confirm the thesis. For example, a study of college men who felt rejected by their parents, as compared with a matched group who felt accepted, showed a reliable difference in favor of the latter group as more nationalistic (Stagner, 13). Similarly, a comparison of nationalistic and internationalist college men revealed numerous evidences that the former group identified themselves with and had generally successful relationships with their parents, whereas the internationalists generally did not so identify themselves, and reported numerous instances of family conflict. On standardized attitude scales, nationalism was found to be negatively correlated with felt antagonism toward either parent.

Active radicals (Socialists and Communists) constitute a group whose antipathy to established national symbols needs no validation. Krout and Stagner (6) gave a lengthy question-

naire on family relations to a number of such young radicals, and to comparable conservatives. The radical group had a much larger number of points of conflict and unpleasant relationships with each parent. This has also been confirmed with standardized attitude scales (Stagner, 13).

The role of displaced personal drives is manifest in such phenomena as the drive for national expansion, prestige and power. The world's outstanding contemporary nationalist, Adolf Hitler, had revealed his identification of himself with the German nation in many passages of his speeches and writings. The classic expression of this attitude, of course, is ascribed to Louis XIV: "L'état, c'est moi!"

The normal development of the individual involves the canalizing of motivational energy (by whatever name) in the direction of specific goals of personal wealth, prestige or other values. In a certain number of cases, presumably because of blockages which have impeded this normal channeling, the goal adopted is the wealth or power of a group. This may constitute the advancement of a labor union, a political party, a church or a nation. The true patriot has identified his own welfare with that of the nation and deflects the energy he normally would expend on personal ambitions toward national goals. This is not, of course, to be confused with the case of an individual who makes use of the nation and the patriotic feelings of his fellows to further his purely selfish aims.

Many, if not most, citizens of modern nations carry frustrated desires for power within them. It is not surprising, therefore, that propaganda delineating a status of superiority has a potent appeal. Our mental hospitals are full of people who create grandiose delusions for themselves; such ideas are not dangerous because they relate only to isolated individuals. Hitler evokes dreams of national or racial superiority to satisfy his own inner needs; these dreams become menaces to world peace because so many less articulate persons find them emotionally gratifying.

As in the case of many psychotics, it appears probable that delusions of grandeur lead to the development of delusions of persecution. The discrepancy between the grandiose dream of what ought to be and the observable reality—if not blocked out by complete dissociation—must somehow be rationalized. So the Russians

develop delusions about a conspiracy of capitalist nations; the Nazis likewise about the western democracies and Russia; the Argentines about the U.S.A., and so on. These delusions serve the purpose of explaining the failure of one's nation to reach its promised greatness, and also to canalize latent aggression against the alleged persecutors. Also as in the psychotic, this mental device serves as an excuse for releasing an overload of pent-up aggression; if one is being persecuted, it is justifiable to attack. Thus nationalists never admit to waging wars of aggression; every war is one of self-defense. (*Vide War and Peace.*)

It is important, in connection with the mythology of nationalism, to emphasize certain irrational and unconscious aspects of the mental processes involved. These features are apparent in the violent emotion aroused by any criticism of the nation as such, attacks on national symbols, or attempts to "debunk" national legends. Any rational debate on the fundamental tenets of the nationalist mythology, particularly in wartime, stirs vigorously aggressive opposition.

Repression and rationalization are manifest in the literature of nationalism; patriotic feeling operates to suppress certain "facts," to distort others and to foster the fabrication of "events" when necessary. Some of the patriotic legends of World War I, investigated afterwards, proved to be pure invention; others were ingenious distortions based upon actual incidents. Under stress of emotion, some aspects of an occurrence are forgotten, others magnified and extended. The resulting tales, however, implausible, are widely accepted because they are satisfying to the recipients. History texts show ample evidence of the same phenomena.

As regards the environmental determinants of nationalism, it is obvious that the educational system plays a leading role. Horowitz (4) has demonstrated the gradual development of fixation on the symbols of the nation and some of the emotional aspects of this process. Meltzer (9) has shown the vague but menacing characteristics in young children's stereotypes of foreigners. Both of these investigators find reason to believe that the schools foster blind devotion to "our" nation, irrational dislike of other nations. Studies such as that of Pierce (11) have adequately demonstrated the preponderance of suggestions antagonistic to all foreign

countries in the textbooks to which school children are exposed. The speed with which totalitarian regimes begin to dictate the content of education is indicative of the recognition of the importance of the schools.

Newspapers and similar media of communication both follow and lead this tendency of public opinion. As Walter Lippmann once remarked, it is safe for the newspaper to denounce acts of foreign nations because the foreigner is neither an advertiser nor a subscriber. Movies need a villain; the foreigner is convenient for the purpose. Even radio serials for children show a predilection for such choices, presumably because the use of accent makes for distinctive vocal qualities. The cumulative effect of all these factors is suggested by Meltzer's study, in which school children characterized various foreign groups as "dirty, mean, cruel." It may even cling on into college, since the data of Katz and Braly (5) show many similar, if less intense, manifestations.

Nationalism is a major counter in political affairs in all nations. In the United States we are familiar with the office-seeker who habitually denounces foreigners and chants the praises of America for the purpose of avoiding debate on concrete issues. He uses—often successfully—the device of labelling his critics "un-American." This technique has been found effective in Britain and France—and was, of course, the outstanding characteristic of Hitler's speeches as candidate in Germany.

This propaganda of newspapers and demagogues would not stir such a profound response were it not deeply satisfying to many individuals. Propaganda is not magic. It cannot create motivational tendencies; at most it can direct them.

A representation of "our country" as opposed to and in conflict with other nations seems to be uniquely acceptable in the customary frame of reference. The process of polarization may be implicit in the development of percepts and concepts in the child. There seems to be some reason for believing that the establishment of one percept as "good" automatically constellates contrasting or opposing percepts as "bad." Thus the child's loyalty to one school facilitates disparaging opinions of competing schools; and one can observe similar reactions in his judgment of communities, churches and nations. Freudians find the basis for this phenomenon

in the ambivalence of the child's reactions to his parents; in the solution of the Oedipus complex, the negative emotional feelings regarding the parents are repressed and only positive emotions remain conscious. The negative affect is then presumed to become associated with individuals, groups or symbols outside the family. On the basis of traditional learning theory, it has been suggested (May, 8) that the favorable emotion predominantly associated with the family transfers to those institutions, groups and symbols which are experienced along with the family. In this view the negative value of foreign nations would have to be explained as a result of adult conversation, newspapers, and education. The intensity of the negative emotion often seems to go beyond this explanation, and to argue for the correctness of the Freudian viewpoint.

The potency of nationalism is the chief psychological barrier to the establishment of a world security organization for collective action against breaches of world peace. As long as the majority of the population in any Great Power has this blind loyalty and devotion to national symbols, including the delusion of national virtue, the people will rally behind leadership pursuing nationalistic aims in the face of opposition from the world organization. Nor will the people of other nations wholeheartedly support collective action except as they see the welfare of their nation directly involved, a condition rarely met in the early stages of aggression.

Many authorities have asked if world peace will ever be compatible with nationalism. The answer seems to be that patriotism, local pride and group cooperation are compatible with world unity if we can eliminate the aspects of aggressiveness and mutual suspicion. Religious fervor has in earlier times led Christians to battle Saracens, and Protestants to war on Catholics. Today religious loyalty is recognized as a desirable emotion, but it does not necessarily connote hostility to other church groups.

The future of nationalism must be similar. We must strive to achieve a frame of reference, for ourselves and for our children, in which nations are perceived as different but not necessarily hostile. We must educate our children for pride in their own social group and its valuable achievements, but also for tolerance and respect regarding the accomplishments of foreign lands.

The solution to the problem of national frontiers is not to exile all persons outside the majority nationality; it is instead to render boundaries less important, so that the exact location of the line creates little tension.

To end wars, we need not abolish nations. We may be able to merge them into an organization of cooperating equals, with certain powers centralized, as England and Scotland once ended their incessant struggle by accepting a single king. Achieving this purpose—true world organization—will require methods of child training, education and public communication drastically different from those prevalent in every western nation today.

NEGRO, THE PSYCHOLOGY OF THE.—The belief that humanity has by nature been divided into races and subraces, and that certain races are inherently superior to others in psychological endowment forms the basis of the racial-difference hypothesis. Racial superiority has been attributed to a number of causes, but in any event the racial-difference hypothesis assumes it is of a permanent nature, resting upon fundamental native differences. An opposite view insists that any apparent differences in psychological characteristics are not biological but are due to culture and the social environment.

History reveals that the belief of racial superiority is very old and well-nigh universal. In recent years it has taken on such tremendous reality and practical significance for many racial groups that they will die in its defense. Moreover, outworn and forgotten racial theories have been revived in an attempt to rationalize political, economic, and social actions and policies. Outstanding among such theories, because of its wide popularization, is that developed in Gobineau's *Essay on The Inequalities of Human Races* (16) and subsequently expanded by Chamberlain (12). Its fundamental contention is the superiority of the white race, Caucasoid, over the other races, and the Aryans (of which the Teutons are regarded as the "purest representatives") over all other whites. The Aryans are the men of reason, honor, ideals, and the true builders of civilization. The black race, Negroid, is given to things of sense and passion; its members see better, hear better, and have a keener sense of smell, but they are capable of fewer of the higher mental processes. The yellow race, Mongoloid, possesses the traits which make for utility, order, and mediocrity. Because races are static and immobile, they cannot be changed. Any effort to mix them meets with disaster. Several writers in the United States have more or less followed Gobineau's pattern (20, 43). Grant (20), for example, glorified the Nordics (a branch of the Teutons), placed them in a class of Platonic guardians and regarded minority peoples as hopelessly inferior.

Opposing Gobineau's point of view are men like Finot (17) in France, Boas (6) and Klineberg (29) in America. In general, these men contend: first, that any differences in psychological qualities are not native or racial but are due to milieu; and, second, that the so-called

proof of inborn inferiority of any one racial group as compared with any other has usually been invented for political or economic reasons, or else is a belief which we naively take for granted.

STATEMENT OF THE PROBLEM

There are so many theories "proving" racial superiority, all in conflict with each other and based primarily on subjective judgment, that one becomes skeptical of their slightest validity. To claim essential racial equality on that account, however, would also be a prejudiced conclusion. Objective data themselves, not specious theories, must be examined.

A good definition of race is hard to give. This, however, is not our concern at the moment. On the contrary, we wish to discuss *The Psychology of The Negro*. Let us call it one aspect of the problem of proving true or false the racial-difference hypothesis. Granted some physical differences between the races, is it possible to find parallel differences in psychological characteristics which can be regarded as part of man's functional nature? Specifically, is there acceptable evidence tending to show a psychological endowment in the Negro race different from that of all other races? Does the Negro exercise functions which are not present in other races; i.e., are there psychological characteristics which are peculiar to the Negro? Does the Negro exercise some psychological functions to better advantage than other races? In short, are there innate qualitative or quantitative differences in psychological qualities between the Negro race and other races?

Some years ago Garth (19, p. 11) envisaged our problem thus as a scientific proposition. Given two races R_1 and R_2 ; an equal amount of education or nurture, E ; a psychological testing device, D , fair to both races; and (as amended by Dearborn and Long 15, p. 531) an investigator who is openminded or free from racial prejudice, O . This gives us upon measurement $R_1 E D O \approx R_2 E D O$. The formula looks innocent enough but in reality it is a poser. In it are the following factors which are difficult to control:

1. *Race*. In the first place we have the factors R_1 and R_2 , two races. We ask what is a race? Although physical anthropologists do not agree upon an exact definition of race, the following

statement would probably be accepted by most of them, namely, that race is a large subdivision of mankind the members of which are distinguished by possessing in common (a) certain distinctive *physical characteristics* which are (b) *determined by heredity* (29, p. 18). Only when both of these facts can be demonstrated do we have a true race. The physical characteristics which have been proposed and applied as criteria of race are many as, for example, skin color, hair texture and color, pigmentation of the eye, nasal form, stature, blood groups, facial and cranial measurements. The difficulty is that the complexities of these physical characteristics from one group to another are so great, and the individual differences within the same group are so tremendous, that no one race can be said to be pure. Whenever the concept is hereinafter used it will be enclosed in quotation marks to indicate that it cannot be applied except in the loosest sense. Some psychologists, e.g., Anastasi (1), take the view that "racial" classification is so difficult a matter as almost to preclude investigation of the problem of psychological differences between "races." For readable accounts of many of the difficulties of "race" classification, see Huxley and Haddon (25), also Herskovits (21).

Perhaps we should also stress the fact that as it concerns the American Negro, the word "race" is a sociological term. Herskovits (24) has shown that this group constitutes a population which is "probably less than one-fourth unmixed Negro descent" (pp. 10-18), and that the average American Negro is as far removed in respect to "racial" traits from the pure Negroid type as he is from the average Caucasoid type. Yet old patterns of "racial" prejudice tend to persist, and those suspected of possessing the slightest strains of "Negro blood" are classified sociologically as Negroes.

2. *Sampling*. If one "race" is to be compared with another, the question of the degree to which any particular group can be taken as representative of the whole "race" to which it belongs becomes a matter of great importance. Should it consist chiefly of individuals whose abilities would be represented either by the upper or by the lower end of a distribution curve of the abilities of the "race," the results would lose much of their significance. We shall return to this problem later and demonstrate especially the danger of extending the results

from one sample of the American Negro to the corresponding population as a whole.

3. *Equality of Nurture.* A common culture implies, not only substantial conformity to tradition, religion, recreation, education, economic status, and the like, for all members, but also adequate participation in cultural opportunities. That the Negro, particularly the American Negro, is subjected to many shocking discriminations can be readily revealed by reading "The Negro in American Life Series" recently prepared under the general direction of Dr. Gunnar Myrdal (23, 26, 28, 35, 42) and sponsored by the Carnegie Corporation. Moreover, it must always be remembered (a) that comparisons are permissible only when environmental differences are absent or at least negligible (7, 9, 11), and, (b) that attempts to equate experimentally for social and culture inequalities of "racial" groups are open to serious question (10).

4. *Fair Measuring Device.* Psychological tests have been subjected repeatedly to criticism on the ground that they are unfair to some "races" examined. A test prepared by a Chinese psychologist would be a measure of what his culture and not a measure of what another culture regards as essential. Moreover, the Chinese would have a decided advantage over Americans in making scores on the test. This is obvious, but what is not so obvious, although none the less a fact, is that a subgroup within a nation such as the American Negro who has had inadequate participation in cultural opportunities will be handicapped in much the same way as one belonging to a wholly alien culture. Psychologists have tended to slight this circumstance because they readily make the erroneous assumption that all compatriots have an equal share in the cultural scheme.

5. *Open-mindedness.* It is difficult for a great many persons to consider the problem of "race" differences objectively since most people, no matter what their "race," have a quick and ready answer to the question regarding fundamental psychological differences. The problem enters into the study of the Negro in a very real manner because of the stereotyping process of both Negroes and whites. According to the popular stereotype or myth (23, 27), the American Negro is an individual of very low mentality. He is considered immoral, or else "unmoral," and is regarded as having criminal

tendencies, being physically unattractive, highly emotional, untruthful, boisterous, over-assertive, bumptious, lazy, happy-go-lucky, and "childish."

It goes without saying that "race" attitudes and judgments of this sort cannot throw very much light upon our problem and will color the results of an investigator who is not free of them.

6. Finally, there is the problem of *interpreting and evaluating the results.* The possible source of errors here is to be attributed mainly to certain assumptions made in the construction and administration of tests. It is *assumed* that the traits tested—for example, intelligence—are inherent; that is, they are not subject to training, and that the individuals who are tested possess *equal* opportunities for achieving. If the traits tested are wholly innate, and if the individuals are not handicapped or penalized by the mechanics of the tests and the test conditions, *then* we are justified in saying we have a fair method of attack. If consistent and reliable differences occur among "racial" groups under such test conditions, we are fairly safe in saying that they are "racial" in determination.

By the time corrections are applied to original measures for the above and other (29, pp. 152-299) factors related to the whole testing situation, the investigator may well wonder at their significance.

METHOD OF PROCEDURE

The problem has been approached in many different ways involving several different though not unrelated disciplines (29, 31). First, attempts were made to infer (or perhaps prove?) inferiority of the Negro by assessing relative contributions to culture or civilization. Then came efforts to find biological differences on the assumption that physical differences between "racial" groups implied psychological differences. Since about 1900 the scientific material has taken, increasingly, the form of psychological analysis through the method of objective tests. The present article is concerned with the last of these approaches and as the same has been applied to Negroes. Studies of other "racial" groups will be mentioned, but only when they raise problems pertinent to the interpretation of the data on Negroes. This article, therefore, should be regarded as an attempt to summarize some of the more important findings in this field and to discuss certain prob-

lems of methodology and interpretation which they raise. Extensive reviews of the experimental literature dealing mainly with intelligence testing have been made by Pintner (38), Canady (8), Witty and Lehman (55), and Thompson (46). For excellent summaries of the whole literature on (a) race differences, see Garth (19) and Klineberg (29); (b) psychological characteristics of the American Negro, see Klineberg (28) and Thompson (46).

The kinds of tests administered have been those to determine the relative keenness of the senses, motor ability, intelligence, musical talent, memory, mental fatigue, aesthetic capacity and disposition, handwriting, achievement, and other abilities. There have been comparative studies of eidetic imagery, emotionality, incidence of mental diseases, personality, "racial" disposition to crime, and other traits.

RESULTS AND DISCUSSION

As we proceed with this summarizing, it will be well to keep in mind as a guide in reaching our conclusions the formula given above ($R_{\text{JEDO}} \cong R_{\text{EDO}}$) and the discussion on the difficulties of controlling the various elements which operate in comparative studies.

Differences in Simple Psychological Functions. Travelers at various times have attributed remarkable superiority to savages and primitive peoples in perceptual functions. These casual observations are important for us because of the popular belief that the development of the intellect in the white man "has occurred at the expense of the simpler forms of psychological activity." A great many attempts have been made, therefore, to find out how primitive and civilized individuals differ from one another in rather simple functions such as sensory acuity (e.g., seeing, hearing, touch, and pain senses), motor ability (speed of reaction and speed of tapping), and simple judgments (such as the form-board test). The studies prior to about 1900 were of little significance, principally because of the small number of subjects (2); but as more and more evidence accumulated after the turn of the century (34), especially Woodworth's (56) study which appeared in 1910 based on a variety of primitive groups tested at the St. Louis Fair in 1904, the popular notion was rejected by experimental results. The conclusion that when proper allowance is made

for training, the sensory and motor abilities of primitive peoples are much like those of more civilized peoples, although arrived at over a quarter of a century ago, still seems to be true.

The early studies of elementary psychological abilities are of interest and value principally because (a) they represent early attempts to discover by means of scientific techniques something of the nature and extent of "racial" differences; and, (b) they demonstrated that "racial" differences in physical traits need not be accompanied by psychological differences, at least of the more rudimentary sort such as those described.

It remains to be seen from the investigations of "racial" differences since 1910 whether significant differences exist in the higher and more complex psychological processes.

Differences in Intelligence-test Scores. In the psychological study of the Negro no other problem has attracted so much attention as the question of the inherent intellectual superiority of whites over Negroes. The amount of investigation engaged in since the advent of the intelligence test has increased rapidly, especially under the impetus of the testing undertaken during World War I, and the experimental literature is extensive. No attempt will be made in this section to give a detailed review of all the studies of Negro intelligence (standing in intelligence test) as excellent summaries are readily available (8, 38, 46, 55). Some effort, however, toward a brief critical examination of both the method and interpretation of quantitative investigations of the intelligence of the Negro in the light of *recent history of intelligence testing* (50) will be attempted here. But first let us give some actual results obtained by the use of tests in this field.

In most cases, the *average* intelligence-test scores of Negroes have been lower than those of whites. In certain localities, however, the Negroes' performance shows no inferiority to that of whites. The recognition of this aspect of the problem was first brought to light by the Army testers (World War I) who found Negro recruits from the North, not only far superior to Negroes from the South but in several instances actually superior to the whites from a number of the southern states (57). The Mexicans, American Indians, and Italians usually obtain the lowest scores, with the Negro definitely above. Several recent studies have

demonstrated that gifted Negro children (I.Q. 140 and above) are no anomalies. As an example of this, the work of Witty and Jenkins (53) is sufficiently convincing. Among 8,000 Negro children, they identified 26 of I.Q. 140 and above, one of whom is a child of surpassing test-intelligence (54).

The methodology employed in attacking the problem of Negro-white "racial" comparison has been simple. The procedure typically followed is to select two groups of subjects, one composed of Negroes and the other of whites. Usually some basis of control, often superficial, is instituted; that is, the two groups may either be within the same age range, or residents of the same locality, or both. A standardized test is then administered to each group, average scores calculated and comparisons made after consulting age equivalents or norms. Any difference found in *average* scores is attributed by one school of thought to the existence of innately determined psychological differences between Negroes and whites, and by another, to the influence of social and cultural background. Incidentally, there has been such a growing number of psychologists who have abandoned the former and once popular school of thought until today it has only a few representatives as, for example, Porteus (39).

It is significant that, almost without exception, all measurements of the Negro have been made with tests standardized chiefly on northern, urban whites. Such a procedure is unjustifiable, for tests are applicable only to individuals similar in their experiential background to the group upon whom they were standardized. When we administer these tests to individuals from widely differing social, economic, and educational levels, we violate not only the original aim of mental testers but also the basic assumption of the intelligence-test method.

Binet was fully aware that his test did not measure innate ability completely divorced from the influence of environment. He postulated modifiability and consistently held that intelligence shows change in relation to shifts in environmental influences (4). Furthermore, he insisted that tests must utilize materials that are appropriate to the environment of the subjects tested, and that tests were valid only for those having essentially the same environment. But when these conditions are satisfied, he considered test-ratings fair measures of com-

parative ability on the reasonable assumption that normal children will be exposed to much the same facts, and hence will acquire much the same information.

It is precisely at this point that the difficulty of making valid group comparisons lies. Even if tests were faultlessly constructed, they would be useful in making Negro-white comparisons when, and only when, the groups tested have had approximately the same schooling and the same common background of experience (55). Two studies on African children have signalized some important factors to consider before generalizing about innate Negro-white differences. In the first, Loades and Rich (32) translated tests from the Goddard revision of the Binet-Simon scale, 1911, into Zulu and gave them to 100 boys and 35 girls at the Adams Mission Station in Natal. They had to change many of the test items "solely because the Binet-Simon Tests are based on cultural conditions not present among natives, or on educational practices not here prevalent." A number of specific instances are given. In the second study referred to above, Nissen, Machover, and Kinder (36) administered a series of twelve performance tests to 50 native West African Negro children living within the area which supplied many Negroes for the American slave trade. Comparison of the tests on which the children did well with those on which they did poorly showed that the difficulty of the tests for the children increased as the content and activities involved were more closely related to the particularized experience of a civilized environment and, conversely, that those tests that are rooted in basic, less differentiated experience common to all "races" in all environments were handled with relative ease and yielded the highest scores in terms of norms obtained with the standardized groups. Thus the presence of cultural and other factors in intelligence tests was demonstrated.

The unsuitability of attempting to evaluate the intelligence produced by one culture in terms of another and the decided advantage to the group in which the test arose are obvious. But what is not so obvious, although none the less a fact, is that a subgroup within a nation that has had inadequate participation in cultural opportunities will be handicapped in much the same way as one belonging to a wholly alien culture. If, therefore, it can be demon-

strated that the experiential background of the American Negro child differs appreciably from that of the white upon whom the tests were standardized, the test results may not be used as a measure of the relative innate ability of the two groups.

Several investigations have revealed that most American Negro children are the products of a narrow and circumscribed world (14, 26); of poor home conditions (18); of poor recreational facilities (58); of an impoverished social and cultural environment outside the school (35); of extremely inadequate schooling (5), and of a poor economic environment (42), with all that this implies in regard to infant and child care, nutrition and health (45). Envisaged in these terms, Negro children approach the tests with a background of early training and environment which varies widely from that of white children and which will be reflected in their responses.

It would seem that the materials on the social conditions of American Negro children leave no choice but to assume that these children are so atypical as not to be fairly measured by existing intelligence tests; yet the precautions given by early mental testers have long been ignored, especially by "Racialists." One of the advances in contemporary testing, however, is the recognition of the obligation to construct and standardize tests that are valid for the culture of the individual. An effort in this direction has been made recently by Shimberg (41).

Differences in Non-Intellectual Traits and Special Abilities.—Recognizing that general intelligence is not the only inherited psychological quality on which success in modern life is dependent, attempts to measure special abilities and temperamental or emotional traits have been made. These have raised questions concerning the Negro's relative ability to exercise inhibitory power, to resist fatigue, to distinguish tones and rhythms, to solve mechanical problems, and the like (13, 30).

Results of comparative studies of *Personality Traits* of Negroes and whites indicate that, while differences appear on the surface, they can be explained as due to environmental factors and difficulties arising from the use of measuring instruments the reliability and validity of which are doubtful and not to "race." Even the study of *Color Preferences* offers no support to the stereotype of the Negro prefer-

ring bright and "barbaric" color combinations. Comparison of large groups of Negroes, whites, Indians, Chinese, Mexicans, Japanese, Filipinos, and other "races" indicates that, while culture may dictate various color preferences as blue for the American Negroes and whites, and red for the American Indians and Turks, the young children of all "races" show striking similarity of preference for colors. No evidence of the Negro's supposedly unusual ability in music has been found; nor have native differences come to light in any of the following characteristics: *speed, mental fatigue, handwriting, mechanical ability, or aesthetics.*

"Race" Mixture and Psychological Characteristics of Hybrids. "Race" mixture, or miscegenation, is a problem which has aroused much discussion in its own right (22, 51). Its advantages and disadvantages have been argued and studied at great length. There is one school of thought which holds that "racial" crossing is pernicious; another, that inbreeding is inadvisable, since new strains must be produced into a population if fertile, virile offspring are to be assured. The truth is that mixture in and of itself does nothing. Whether the genetic consequences are good or bad depends entirely upon what genes enter into the mixture. This means that, in the light of present knowledge concerning the inheritance of traits in man, the type of offspring to be expected from Negro-white or other crossed groups is dependent upon the endowments of the parent stocks on each side of the breeding process. "If the ancestors were capable members of their racial stocks, their crossed descendants will inherit the capabilities of their forebears. Conversely, a population may be ever so purely bred, and yet if the capabilities of the ancestors of that population were of a low order, the pure-bred stock will be poorly endowed for all its racial purity" (22, p. 402). Incidentally, the "racial" source of the Negro contribution to the process of hybridization in the New World has been investigated by Herskovits (23). He finds that the American Negro is not, as popularly supposed, a man without a past. His African ancestors were very capable people and brought here with them a cultural background that is to be regarded as highly sophisticated.

Psychological studies of Negro-white "mixed bloods" may be divided into those that deal with the relative intellectual capacity of mixed

before making comparisons. There seems to be no basis, however, for this procedure (10).

Position of Anthropology and Specialists on "Racial" Psychology. In 1930 Thompson (47) circulated a questionnaire among "competent scholars in the field of racial difference" which revealed that only 4 per cent of the respondents believed in "racial" superiority or inferiority. He concludes:

"... The data reveal unmistakably that it is the general conclusion of scholars engaged in the field of racial differences and closely allied fields that experimentation to date has neither demonstrated that there are any *inherent* mental differences between American Negroes and American whites, nor corroborated the "mulatto hypothesis"—that Negroes with more white blood are *inherently* mentally different from Negroes with less white blood—which is a fundamental corollary of the racial-difference thesis." (P. 511.)

At the 1938 annual meeting of the American Anthropological Association (44), a resolution was unanimously adopted, in part, as follows:

"(1) Race involves the inheritance of similar physical variations by large groups of mankind, but its psychological and cultural connotations, if they exist, have not been ascertained by science . . .

"(3) Anthropology provides no scientific basis for discrimination against any people on the ground of racial inferiority, religious affiliation, or linguistic heritage." (P. 30)

Recently, a group of psychologists prepared a protest against the "non-scientific interpretations" of "racial" psychology which "Fascists are using to justify persecution." The protest was prepared by psychologists who are specialists on "racial" psychology and was issued officially by the council of the Society for the Psychological Study of Social Issues. It reads (48), in part, as follows:

"In the experiments which psychologists have made upon different peoples, no characteristic, inherent psychological differences, which fundamentally distinguish so-called 'races' have been disclosed. . . . There is no evidence of an inborn Jewish or German or Italian mentality. Furthermore, there is no indication that the

members of any group are rendered incapable by their biological heredity of completely acquiring the culture of the community in which they live. This is true not only of Jews in Germany, but also of groups that actually are physically different from one another." (Pp. 7-8)

The position of American anthropology and specialists on "racial" psychology is thus clearly stated. It is that scientists have not ascertained whether differences in psychological characteristics exist among the "races" of men. More specifically, the position would be that it is at present wholly unknown whether there are differences in psychological functions as related to biological variations in "race." Furthermore, it seems safe to say that recent history of the scientific study of the Negro represents an increasing trend toward the repudiation of all positive findings with respect to "racial" differences.

CONCLUDING STATEMENT

This very brief summary of the vast amount of experimental material on the psychology of the Negro makes clear at least some of the difficulties in the way of evaluating the comparative psychological endowment of the Negro and other "racial" groups by means of present methods of study. Until and unless the various factors affecting the results are adequately controlled, such comparisons will have little meaning; meanwhile, probably the best thing is to act as if all "races" had equivalent psychological qualities. Thus, when all attempts to find inherent differences in psychological characteristics between Negro and other "races" are taken into account, the verdict of *not proved* is the only one that can be given at this time. But we must keep our minds open, and be prepared sometime to have it proved that, in some characteristics at least, there are marked divergencies.

P

PARAPSYCHOLOGY (a division of psychology dealing with the paranormal—those psychological effects which appear not to fall within the scope of what is at present normal and recognized law).

HISTORY

Among primitive peoples many experiences occur which suggest the reality of a mode of psychological functioning distinct from the ordinary contact of the senses, and of behavior, with the environment. Dreams or waking impressions may appear to forecast the future, or thoughts may appear to be caught from the mind of a distant person. Objects also seem at times to move as if acted upon by a purposeful but invisible agency. Either of these types of phenomena may suggest to those who experience them the action of discarnate intelligences. The Greco-Roman world, and ancient India and China, were very familiar with experiences of these same types. They engaged the attention, for example, of Aristotle and of Cicero; and though frequently condemned as the work of malign spirits, continued to interest the thoughtful until the rise of modern science in the seventeenth century tended to make the literate public hostile to reports of such experiences. Yet events of these types continued to be reported in large number, and by men worthy of attention, such as Ben Jonson, Goethe, and Linnaeus.

The nineteenth century could no longer tolerate the attitude of simple negation, and efforts towards a scientific investigation of this borderline area of knowledge began to take shape. Sir William Barrett (2) reported successful experiments in telepathy, and Sir William Crookes (12) described observations of materializations produced by a medium. In 1882 a group of scholars largely drawn from Cambridge University founded in London the *Society for Psychical Research*, an organization devoted to systematic inquiries into alleged paranormal phenomena of all the types mentioned above.

Prominent in the group were Henry Sidgwick, Frederic W. H. Myers, and Edmund Gurney. William James shortly thereafter participated in the organization of a similar society in the United States. This latter soon became a branch of the London Society, with research mainly in the hands of Richard Hodgson. After Hodgson's death in 1905, an independent American Society for Psychical Research was organized by J. H. Hyslop. The London and American societies publish Proceedings for general circulation and a Journal for the membership. An *Institut Metapsychique International* publishes in Paris the *Revue Metapsychique*. These three organizations, together with the Parapsychology Laboratory of Duke University, constitute the chief research centers today. Cambridge University has continued to play a part in such investigations; from Harvard University, Stanford University, and the University of Colorado has also come a considerable volume of research in this field. Psychical research organizations have been founded in some thirty countries, and, beginning in 1921, four international congresses of psychical research have been held.

SPONTANEOUS TELEPATHY

In 1882 it became the task of a committee of the (London) Society for Psychical Research to conduct a systematic study of the extent and nature of impressions appearing to involve contact between one mind and another through channels other than the senses; the results were published in Gurney, E., Myers, F. W. H., and Podmore, F., *Phantasms of the Living*, 2 vols., 1886. Partly by published notices, partly by consulting biographical and other records, but very largely by person-to-person inquiry conducted by a large group of volunteers, cases of apparent paranormal contact between persons were gathered. The first such person-to-person inquiry reached over 5,000 individuals and netted many experiences suggesting such apparent contact. A typical case of spontaneous telepathy (20, I, p. 188) is that of a woman who woke

suddenly with the impression of receiving a violent blow on the mouth. Two hours and a half later her husband came in from boating, his lip bleeding from a blow caused by the tiller of the boat. The time agreed well with the time of the wife's awakening. A case thus corresponding with fact was called *veridical*. Statistical evaluation of the hypothesis that these are due to sheer coincidence (impressions bearing no functional relation to the facts) is difficult in the case of events as infrequent and poorly recorded as are impressions of blows upon the mouth. With one class of experiences, however, statistics are feasible; namely, impressions of the death of a distant person when no knowledge of his illness or of danger to him is available. A woman awoke with a feeling of sadness; an hour or so later she had a vision of her brother tripping over a rope and falling, and exclaimed that he was drowned (35, I, p. 283). In point of fact, her brother, on a harbor boat, had in the early hours of the morning been caught by the tow-line, thrown from the deck, and drowned. The number of such veridical impressions of death was large.

The statistical question is defined by the death rate: the likelihood that a person X will die on a given day. The inquiry covering a twelve-year period treated dreaming and waking impressions separately. The investigators wished to know first how common it was to have a dream coinciding (within twelve hours) with the death of an acquaintance. To 5,360 persons the question was put, "Since January 1, 1874, have you ever had a dream of the death of some person known to you, which dream you marked as an exceptionally vivid one, and of which the distressing impression lasted for as long as an hour after you rose in the morning?" An affirmative answer was given by 173 of the respondents. After excluding some cases not meeting the requirements, it was concluded that about one respondent in each 26 should be included in the affirmative category. The probability that a person taken at random will vividly dream of death in this way in the course of 12 years is about one in 26. Now in terms of the death rate (22 per 1,000) the probability that any given person dreamt of will die within 12 hours of an assigned point of time was about $22/1,000 \times 1/365$; hence the probability that, in the course

of 12 years, a specific vivid dream of death and the death of the person dreamt of would fall within 12 hours of one another was $(1/26)(22/1,000)(1/365) = 1/431,363$. After further analysis, they concluded that each group of 431,363 persons in the United Kingdom would by chance produce one such coincidence in the given time. Now if the appeal for evidence had effectively reached as large a section of the population as this—431,363 who had such experiences to communicate—the number of such genuine death coincidences which ought, by the theory of probability, to be encountered, is 1. The number actually encountered in the whole investigation among all sources—of vivid dreams of death, by persons free from anxiety, and falling within the time limit—was 24. It was pointed out that there might well be a general tendency to remember veridical and to forget non-veridical cases. But the yield of so many veridical cases could be explained on a chance basis only if Englishmen have on the average many distressing dreams regarding the deaths of those with whom they are acquainted. Yet in fact the very data from which these computations are made show that most individuals replied to questions about such experiences by saying that they had never had such a dream, either veridical or non-veridical.

And many of the dreams were not simply dreams of death, but produced very specific correct details as to the cause of death. Statistical treatment of *hallucinatory* (waking) experiences of death followed similar lines, and led to a similar result. This early study was noteworthy for its extensive and subtle analysis of the telepathic process. Much use was made of the newer knowledge of dissociated and sub-conscious phenomena, to which Azam, Richet, and Janet had already given much attention. It was pointed out that the phenomena belonged to a psychological realm outside of the ordinary conscious sphere of activity. There was, however, a sharp difference of opinion between Gurney and Myers as to the *collective veridical hallucination*, e.g., in which two or more people, together at the time, experienced veridical hallucinations related to the same distant happening. Gurney argued that one percipient received the impression and transmitted it to the others; Myers, that the agent in some sense invaded the region where all the percipients were.

Another extensive survey of spontaneous telepathy was published in 1894 in the *Proceedings of the Society for Psychical Research*, under the title, *The Census of Hallucinations*. This contained many new veridical cases and a similar statistical analysis, indicating the implausibility of a chance interpretation. Since that time the London and the American societies have continued to publish current spontaneous cases each year. In 1931, W. F. Prince (45) published a survey of such cases (and cases of related types) based on a questionnaire addressed to 10,000 persons in *Who's Who in America*.

As to the psychological basis for such spontaneous telepathy, these many studies appear to indicate: (a) that the motivation, the need for contact on the part of the percipient, the agent, or both, plays a large role; (b) that sleep and semi-sleeping conditions are highly conducive to such impressions; (c) that waking states of dissociation such as the "brown study" or extreme absent-mindedness are favorable; and (d) that certain involuntary dissociated activities—"automatisms"—such as writing and hallucinations stimulated by a bright surface such as a crystal, allow impressions which have been received at a deep level—in Myers' language, received by the "subliminal" (35)—to work their way into the channels of expression. The most systematic study of the *modus operandi* of spontaneous telepathy, particularly as it relates to apparitions seen at or after the time of a distant person's death, is the work of G. N. M. Tyrrell (75).

EXPERIMENTAL TELEPATHY

But the gathering of spontaneous cases appears unsatisfactory from the point of view of establishing clearly the dynamics of the process or processes involved. As in other branches of psychological research, experimental methods are demanded if basic principles are to be clarified. For this reason the study of spontaneous cases has tended to be more and more subordinated to the experimental study of telepathy and related problems. Between 1882 and the end of the century numerous experiments in telepathy were conducted in Great Britain, the United States, and Germany; for the most part, impressions of drawings were to be transmitted. In the nomenclature developed, the *agent* or transmitter undertook to convey the impression to the *percipient* or receiver. Occasionally such studies assumed statistical form, and occasion-

ally they threw light upon the psychodynamics of agent or percipient; many such studies indicated, as we noted in relation to spontaneous experiences, that dissociated states are especially favorable. Early in the present century Miles and Ramden (34) reported long and striking series of experiments, while Usher and Burt (77) gave especially striking evidence that dissociation was of special importance.

The last named investigators described an experiment that had been set for 8:30 p.m. During the day preceding the experiment, the percipient B told his friend C that an experiment was to take place and that she might take part if she wished. The agent A, who was at a distance of several hundred miles, did not, of course, know of C's participation. That evening A dined in a little Bohemian restaurant, and after dinner began a game of chess at the same table. At an adjoining table three men were talking loudly; they were eating roast capon with bread sauce. The room had green hangings. In the next room someone was strumming on the piano. At 8:25, A suddenly recalled that the experiment was due and hastily withdrew to a quiet place. Here at 8:30 he concentrated on a diagram. The impression received by C in automatic writing included the following items: "Roast capon, bread sauce, three men, much talk, green hangings, somebody strumming." With it was a crisscross pattern resembling a chess board. Now the important thing dynamically, in this as in many other cases, is that nothing was received at the conscious level; the whole communication came through automatic writing.

In 1921 and thereafter, René Warcollier (80) developed this conception experimentally and theoretically. He established in Paris a group for telepathic studies, which, in collaboration with "telepathic posts" scattered throughout Europe, studied the nature of telepathic images and of the relaxed and dissociated states in which they tended to appear, and a series of transatlantic experiments with a New York group was reported to the Third International Congress of Psychical Research in 1927. To the same period belongs the careful study by Dr. Carl Bruck (5), of Berlin, of the telepathic powers of four subjects under hypnosis, as compared with their powers in the normal state. Very complex drawings prepared and placed in a portfolio in another room were in many in-

stances reproduced with great accuracy. But the best subject did about as well in the normal state, and neither this nor the later studies by Rhine (49) and Grela (18) seem to settle conclusively the question of the utility of hypnosis for such research. Bruck's data do, however, strongly support the view (a) that the motivation to succeed was intense, (b) that very extreme concentration on the task was essential. In the same direction point the many tests of the powers of the Polish sensitive Stefan Ossowiecki, who through the 'twenties and 'thirties gave many demonstrations under good conditions. For example, a lightproof packet was prepared by T. Besterman (4) in London, in the form of a slip of paper enclosed within three envelopes. The paper contained a drawing of a bottle of Swan Ink. Lord Charles Hope, with this in his pocket, tested Ossowiecki in Warsaw. In his state of concentration Ossowiecki drew the bottle and the letters SWA IN. There are many such scattered tests; but only when the working conditions are well described do they throw light on the dynamics of the processes involved.

During the first World War, experimental studies of telepathy were reported by J. E. Coover (10), at Stanford University, and by L. T. Troland (74) at Harvard, both using methods permitting statistical treatment of results. While Coover's data showed success in guessing playing cards at a level four P.E. above chance expectation, he concluded against interpretation in terms of a paranormal result. Troland's very limited data are hard to interpret. An important forward step was taken by three psychologists (6) of the University of Groningen in the Netherlands who, in 1921, presented to the First International Congress a series of well-controlled studies involving the transmission of material which could be appraised from the statistical viewpoint. Two rooms in the laboratory were used, one directly above the other. A hole was cut in the floor of the upper room and two sheets of glass placed therein, with an air cushion between. It was thus possible to look from the upper into the lower room, but no voice could be heard in the lower room even when one shouted. The psychologists took turns as agent; a student of dentistry was the percipient. The materials to be transmitted consisted of letters and numbers arranged on a board as indicated in Fig. 1.

6	6	6	6	6	6	6	6
5	5	5	5	5	5	5	5
4	4	4	4	4	4	4	4
3	3	3	3	3	3	3	3
2	2	2	2	2	2	2	2
A	B	C	D	E	F	G	H

In each experiment they drew from a bag a slip of paper determining which letter, from A to H, and from another bag a slip determining which number, from 1 to 6, was to be used. The two slips together thus designated one specific square on the board. In the room below was a wooden framework covered with black cloth on its upper and three lateral surfaces. The chair of the blindfolded percipient was placed so that his back was to the open side. His right arm extended through an opening so that the hand and a part of the forearm were visible to the experimenters in the room above. Before the percipient's hand lay the board just described. The purpose of the experimenters was to impel the subject by their own volition to move his finger to the square which had been chosen by lot and upon which they were concentrating their attention. The percipient's signal that his choice had been made was a double tap with the forefinger upon the board; thus no premature termination of a given experiment could result in a spurious success. Six experiments at a time were carried out under these conditions; the experimenters then came into the percipient's room and performed six experiments at close range, changing the position of the board upon entering as well as upon leaving the room (throughout the experiment these two conditions alternated). Of 187 experiments conducted, one in 48 or approximately 4½ in all should have been successes according to the theory of probability. Actually, the number of successes was 60. Curiously enough, 40 per cent of the experiments between two rooms were successes, but only 30 per cent of those in the same-room condition. The experimenters suggested that in the latter case the attempt to

be on their guard against unconscious whispering, and the like, had perhaps interfered with their concentration. Over and above the number of complete successes, the amount of deviation upon the board from the correct square was noted in the case of all errors, and it was found that the distribution of errors followed a normal probability curve; deviations of one square from the correct square were much commoner than deviations of two squares, etc. Alcohol was used in a few trials and seemed to have a markedly beneficial effect on the results; in fact, of the 29 trials in which the subject took 30 grams of alcohol ten minutes before the experiment began, 22 were successful. Upon this the investigators comment: "Alcohol overcomes the individual's normal inhibitions. The decrease in self-consciousness and the tendency to more superficial ideas are symptoms of this lack of inhibition." The subject's reports of "passivity" or "relaxation" also coincided well with his most successful efforts; a study of the galvanic skin reflex gave results which seemed confirmatory to this view (7). At the same time he was apparently in full "concentration" upon the task.

These studies were followed by the work of G. H. Estabrooks (15) at Harvard, likewise using separate rooms for agent and percipient, and obtaining statistically appraisable results. Playing cards were used as "targets" (material to be guessed) with 83 subjects, each guessing 20 cards from a complete deck shuffled and cut. The most striking feature of the results was the huge excess of correct guesses (of color and suit) over chance expectation in the case of most subjects' first ten guesses; during the second ten guesses a rapid decline of scoring successes regularly occurred (such "decline effects" have many times been repeated).

THE DUKE UNIVERSITY EXPERIMENTS AND THEIR SEQUELS

The investigation of experimental telepathy was revolutionized and redefined by the studies conducted at Duke University from 1930 forwards by J. B. Rhine, the first report appearing in a volume entitled *Extra-Sensory Perception*, 1934. Using sets of 25 cards, each card bearing one of the five symbols, ☆ □ ≈ + O, he and his associates tested the effect of many physical and psychological variables upon a very large number of subjects, adult and child, normal and abnormal. It became a consistent part

of experimental procedure to include in the larger studies some preliminary investigation with no attempt at perfection of experimental control, followed by large masses of results using rigid controls (these will be described briefly in connection with each experiment noted below, but the original papers should be consulted).

But the word telepathy does not suffice to classify Rhine's work. Though telepathy has been studied, many of the Duke University experiments were carried out under conditions chosen to preclude knowledge of the stimulus materials on the part of the experimenter as well as the subject. Decks of cards were, for example, shuffled by the agent but not looked at during the test, or in other cases shuffled by a third party and handed face down to the agent. In many cases cards were placed behind screens or concealed individually in opaque envelopes, the order of the symbols upon them being known to no one.

One of the recurrent problems was the effect of distance. Accordingly, the subject Hubert Pearce went to a room in the Duke University Library while the experimenter, J. G. Pratt, established himself with the cards in the Physics Building one hundred yards away, in a room facing away from the library. Their watches were synchronized. The experimenter would take the top card from a shuffled pack of ESP cards in the room agreed on and lay it face down on a book in the center of the table without looking at its face. Thirty seconds later the subject in his cubicle in the Duke Library would record a call for the card. At the end of the minute, the observer would remove the card and take the next one. The cards as removed would be kept in order for later recording. Two runs, of 25 calls each, were made per day. Pearce's record and Pratt's record were both made in duplicate and were independently submitted to Rhine, scored and photostated. The hits in this first series by runs of 25 were as follows: 3, 8, 5, 9, 10, 12, 11, 12, 11, 13, 12. Since the expected number (by chance) is 5, a score of 11 or better should occur about four times in 700 runs. A second such series was performed under the same conditions but with the experimenter and cards 250 yards away in the Duke Medical Building, and the scoring level was again such that an experimenter should not expect to see it arising by chance once in a lifetime. In all, four such long-distance series

with Pearce were done, as shown in Table I; each may be compared with the "same room" condition (Group E). Distance appears unimportant (52).

TABLE I

Group	Conditions	Number of Trials	Average
A	Physics building and library	300	9.9
B	Medical building and library	1100	6.7
C	Physics building and library	300	7.2
D	Physics building and library	150	9.3
E	Same room	900	8.2

The large number of experiments yielding significant results by these methods was offered as warranting the conclusion that direct clairvoyance is possible, the subject making contact somehow with the stimulus materials, not with the mind of any person. Rhine concluded that in many earlier experiments purporting to test telepathy the results could have been achieved either by telepathy from the mind of the agent or by clairvoyance, or by a combination of the two. The classical type of experiment in which the agent looks at the target material might be regarded as ambiguous; Rhine classed such experiments under the term "general extra-sensory perception."

Rhine experimented on the influence of drugs (51) upon scoring level (sodium amylal reducing the scoring level of good subjects, and caffeine tending to restore it), and made extensive comparison between different methods of "calling" (making guesses), such as: DT (down through), in which the subject guesses each card in a face-down deck from top to bottom; open matching (OM), in which face-down cards are matched, one at a time, against the five key cards; and BM (blind matching), in which the cards are matched against key cards whose faces are likewise not observed (in all but informal preliminary studies, the key cards are concealed behind a screen or placed in opaque envelopes). He was able to show that determination to obtain a below-chance score could be as successful as an effort at high scores.

The publication of *Extra-Sensory Perception* and of many articles in a journal founded in 1937, entitled the *Journal of Parapsychology*, marked the organization of a vigorous movement for studies of experimental problems in

psychical research, the term parapsychology tending to be identified with the experimental aspects of the field, though frequently (as in the case of the present article) it has seemed best to include spontaneous and experimental data in their interrelations. The *Journal* has carried reports from some twenty departments of psychology. While these many studies cannot be reported here, the University of Colorado study by Martin and Strubic (33) requires mention, for in screened DT studies over three years, some 250,000 calls, from several hundred subjects, were obtained, with a CR of 45.70 (as compared with a CR of 1.00 from control data) and with an intensive study of the performance of one high-scoring subject for the whole three-year period.

Criticisms of the work (e.g., 30, 31, 44, pp. 183-241) have been numerous, notably in terms of (a) selection of data from certain subjects, withholding data from others; (b) faulty statistics; (c) errors in recording; (d) loose method in exclusion of sensory cues. A full appraisal of these matters is not feasible here, but it may be indicated (a) that the original 1934 volume *Extra-Sensory Perception* published all data secured by the methods reported and that the same practice seems to have been very consistently followed by the *Journal*; (b) that the statistical issues, dealing chiefly with the question whether the standard deviation for the deck of 25 cards should be 2.00 or 2.04, or between the two, have never been shown to be pertinent to the experiments offered as clear evidence, in many of which critical ratios of 5.00 and higher have been achieved; (c) that recording errors appear chiefly to take the form of occasional omission of a hit; and (d) that hundreds of thousands of calls have been made at long distance or with screened or concealed cards.

Since 1938, when a round-table on ESP methodology was held at the meetings of the American Psychological Association (16), emphasis has been placed upon studies simultaneously meeting such objections; for example, by using two experimenters, numbered record sheets, and two independent checkings of data. In an especially well-planned study, for example, by Pratt and Woodruff (43), showing the influence of novelty of target material (in that scoring level rises with the introduction of each new task in a series of tasks), very rigid condi-

tions were in force. Two experimenters participated. The subjects used a matching method, the key cards being placed on the subject's side of a screen, while the experimenter, on the other side, placed each card in a face-down deck opposite one of the key cards as directed by the subject; the subject made his call by indicating with a pointer thrust beneath the screen (screened touch matching, STM). The experimenters' faces were not visible to the subjects. Serially numbered, identifiable record sheets were used and triple score records made. No omission or selection of data could have occurred. The data from 32 subjects gave a critical ratio of 4.99. The issue has therefore melted down largely to the question of belief in the competence of the experimenters. Since many groups of investigators, aside from those at Duke, are concerned, the issue appears to be a question of the amount of evidence required to overpower the huge *a priori* incredibility of the phenomena. (For an over-all survey of ESP research up to 1940, v. Pratt, J. G., Rhine, J. B., Smith, B. M., Stuart, C. E., and Greenwood, J. A. *Extra-Sensory Perception after 60 Years*, 1940.)

PSYCHOLOGICAL FACTORS IN SCORING-SUCCESS

In an attempt to discover favorable psychological conditions, numerous studies (e.g., 42) have dealt with the influence of the personality and manner of the experimenter when different experimenters employ the same external control of conditions, yielding evidence that one experimenter can obtain consistent significant results while another cannot. Typical of the many studies dealing with motivation is one by Price (44, p. 283) with 25 children, the method being screened open matching. When children worked alone, the average score was 5.2; in a competitive situation 6.5. There has been a huge amount of study (44) from several laboratories, of "decline curves" (of the sort described by Estabrooks, *vide supra*), pointing apparently to loss of interest on the part of the subject; and there has been much evidence of the Gestalt principle of perceptual organization, in that relatively more of the first and last calls in a series of 25 than of the intervening calls are correct (51). Likewise, when the record sheet is marked off for groups of five calls, the first and last calls in each segment of five are influenced by ESP more than are the intervening calls (decks be-

ing inaccessible to the senses); these effects are designated *run salience* and *segment salience* (53).

It must be stressed that no completely satisfactory "repeatable" experiment has yet been devised, such that any experimenter could, by following specifications, assure himself of a positive result. Much effort has been devoted to the problem, of which G. R. Schmeidler's work will serve as an example. The primary hypothesis formulated by Schmeidler (58, 59, 60, 61) was that when tested by equally rigid procedures, those believing in the possibility of paranormal phenomena should be expected to give themselves to the task with greater freedom than those who reject the theoretical possibility of the paranormal, so that in time significant differences in scoring level between these two groups should be achieved.

The method was to place decks of 25 cards—or simply lists of such symbols—in concealment (in a room or closet away from the subject) and to require the subject to guess the symbols in order. Lists of random numbers were used by an assistant in preparing these decks, so that the experimenter herself could not at the time know their order.

When it began to be evident that the data were consistently conforming to the expectation, an additional series of subjects was deemed necessary; and not being content with a single repetition, the experimenter has since that time made use of one new series of subjects after another. Six extensive series of tests, no one of which comprised less than 200 runs of 25 cards each, were performed. Each such series gave results in conformity with the hypothesis. The tables below give the number of subjects, number of runs, critical ratio and p-value for comparison of the groups differentiated by attitude. It is the *consistency* of the difference between the two groups, always in the same direction, that should be stressed.

The six series therefore constitute a repeatable experiment in the ordinary use of the term. The effects, in absolute terms, are slight; indeed, the paranormal would probably never have become a controversial problem if the effects with ordinary normal people were large. But they seem to be as consistent as human material can be expected to be. Exactly what conditions must be fulfilled it is as yet impossible to say; there are many unspecified factors to be discovered. With

TABLE 1

Scores obtained in a card-guessing experiment by subjects who, in this experiment, accepted the possibility of paranormal experience and by subjects who rejected the possibility of paranormal success in scoring.

A. Subjects who accepted the possibility of paranormal experience.

	Series 1	Series 2	Series 3	Series 4	Series 5	Series 6
Number of Subjects	13	13	22	9	23	19
Number of Runs	129	127	133	162	207	171
Deviation from "chance expectation"	+56	+33	+31	+34	+45	+27
Mean Score	5.43	5.26	5.23	5.21	5.22	5.16

B. Subjects who rejected the possibility of paranormal experience.

P _{DIFF.}00002	

their discovery, increasing control should be possible. But that one important factor is attitude seems clear. These studies are illustrative of the contemporary emphasis upon attitude, and behind attitude, *personality*, as a fundamental factor in paranormal functions. Considerable work on the personality factor is in progress, notably through the Rorschach test, the Thematic Apperception test, and the Rosenzweig Picture-Frustration test.

WHATELY CARINGTON'S FREE-DRAWING METHOD

Most modern work in ESP has made use of prepared target materials permitting a simple statistical treatment: playing cards, Duke University ESP cards, or the like. It has, however, been very generally felt that completely free material—for example, drawings freely executed by the agent—might have many advantages;

certainly in their use boredom and various types of blockage could more easily be obviated. The use of these methods, however, alters the statistical problem. It is, for example, necessary to know how commonly a large group of normal people will think of and draw each of the various objects used in an experiment. Among the efforts to cope with this problem of evaluating free drawings are J. G. Pratt's (41) analysis of the material gathered by C. H. Rice, and C. E. Stuart's (67) preferential matching method. Whately Carington (8) has for a number of years devoted himself to the development of a suitable technique for long-distance tests of telepathy in which the agent, taking material from a large collection of words indicating drawable objects, executes ten drawings, while by prearrangement a large number of scattered and distant percipients draws at corresponding

times the impressions received. Having derived empirically from a huge mass of material a catalog indicating how often each item appears in such free drawings, he has made it possible to apply to the hits on each target-item a formula developed by R. A. Fisher:

$$(h-np)\log\frac{1}{p}$$

where h represents hits, n the number of calls made, p the probability (based on the catalog) that the call will be correct by chance alone; the variance is

$$(npq)\log\frac{1}{p}$$

where $q = 1-p$. It is now possible to assess approximately the total result obtained. The target material must, of course, be selected by some random method, so that under conditions excluding telepathy the likelihood of drawing a specific object such as a broom or an armadillo, at the moment when it is actually used, is no greater than at another moment when it is not used. With large masses of material, the data show that the method is practicable; control drawings do not correspond with the originals more than they should on a chance basis. Actually, however, in a long series of such tests with many different groups of subjects, Carington and a group of collaborating psychologists have been able to obtain repeatedly very striking results, indicating that the responses given by the percipients on a given evening do in fact significantly agree with the material prepared and used on that particular evening. The British results have been so consistently successful as to warrant the hope that this might constitute a genuinely "repeatable technique." But in view of the ambiguous results obtained by an American group who used this procedure (71), the question of repeatability is not yet settled.

PRECOGNITION

Among recent studies engaging the attention of the Duke University group and of several other investigators in the United States and Great Britain has been the problem of precognition, or direct perception of future events (not simply inference regarding their probability). One method has been to evaluate predictions of the order of cards which are to be shuffled later. Having obtained positive results by this method (57), the Duke University group

determined to eliminate any possible effect of the percipient upon the behavior of the experimenter who shuffled the cards. In consequence, the determination of the target order was made by a motor-driven machine (50) in which dice, determining the target order, came to rest in a manner not normally predictable; the targets were set up at various intervals after the original calls had been made. Under such conditions, also, significant results have been obtained. But the deviations from chance expectation in individual runs tend to be slight, the very significant results being achieved through accumulating large masses of data under uniform conditions. The effect of salience has been striking in such precognitive calling (50).

Precognition has also been extensively studied by Soal (64), and by Soal and Goldney (65) in England, in the form of precognitive telepathy (contact with another person's mental operations as of a later time). In the former study it had been found that a subject consistently made hits not on the specified target item, but on the item which followed, and precognition seemed to fit the situation better than did other hypotheses. In the latter study the subject under observation by one experimenter in one room made his calls; in another room another experimenter, under observation by still another person, drew counters of various colors from a bag in order to determine the target card. There was a marked and consistent tendency to hit not the target exposed at the time, but the one which came next. In another series, random numbers unknown to the experimenter determined the order of stimulus presentation; again there was displacement to the next target. The scoring level was of a very high order of significance in both series. The acceleration of the tempo of calling resulted in the subject's calling not the item immediately following the target item of the moment, but the item which came *two* steps later, suggesting that the constant in this individual case was the time duration between the moment of call and the moment of exposure of the target item. This finding is reminiscent of a study of C. E. Stuart (68) indicating that for success in ESP scoring there is, for each individual subject, an optimal tempo of calling.

PSYCHOMETRY

The term "psychometry" was coined some seventy-five years ago to describe the ability of

certain sensitives to give detailed information about persons when holding some object which had once been worn or owned by them. Thus Osty (36, pp. 104-109) handed to Mme. Morel the scarf worn by an old man who was lost; she gave a detailed description of the path he had taken through the forest, and his body was found. Similarly, in the studies of Pagenstecher (37) and W. F. Prince (46), Señora de Z., holding various objects, gave very detailed reconstructions of past events related to these objects of which neither she nor the experimenter could have had any knowledge; the reconstructions were subsequently verified. In 1940, Hettinger (21) carried out extensive experiments of this type with two sensitives in London, treating the data statistically in such fashion as to show that the statements made about the owner of each object were significantly more relevant to the owner than to control persons. It is currently held by numerous investigators that such results are simply a special case of telepathy.

PSYCHOLOGICAL PRINCIPLES IN ESP

As to the psychological laws apparently revealed by all the work on ESP (telepathy, clairvoyance, and precognition) up to the present time, the following would appear to be on rather safe ground: (1) Telepathy, clairvoyance, and precognition are closely related; they are similarly affected by various conditions, and stem from a common psychological matrix. (2) The optimal condition for their appearance is one involving both concentration and relaxation, in the sense that the task draws upon a level of activity in which the individual is completely absorbed in single-minded attention to the task. It might be more accurate to say, with C. E. Stuart (69), that "'concentration' and 'relaxation' are the 'dramatics' of ESP rather than optimal conditions for ESP. The matter of individual attention is important, but the particular device for accomplishing this is probably a matter of the individual personality." (3) The value of dissociated states, which appears in some studies to be great, probably lies in their predisposal to a state which thus permits complete devotion to the task. (4) Favorable motivation—whether conscious determination to score well or unconscious disposition toward the task as revealed clinically—is a variable of major importance. (5) Attitude toward the experimenter appears to influence such motivation

profoundly. (6) Attitude toward the task itself is also a major variable. (7) Individual endowment varies greatly.

INTERPRETATIONS

As to the systematic views which have developed regarding the nature of the phenomena, it is necessary to distinguish between those which attempt a straightforward psychological account of what happens and those which attempt to grapple with philosophical questions. As to the former, three current conceptions are worth noting: (1) Rhine (51) has emphasized the extra-physical properties of ESP as shown by its independence of distance and time (as far as it has been tested). He and his associates have stressed the configurational aspects of ESP performance, as in the case of decline curves and salience ratios, and have thus tended to put Gestalt psychology to work in clarifying the dynamics involved. (2) Associationist interpretations have been invoked, notably in W. Carington's (6) recent thesis. He stresses the apparent fact that all the mental phenomena of parapsychology behave *as if* the basic laws of association operated in exactly the same way whether a given mental content is all in one mind, or part of it in one, part of it in another. Carington notes that if the agent looks at or thinks of a word X to be "transmitted," at the same time associating this with some other object, called a *K-object*, and if the percipient at the same time perceives or thinks of a similar *K-object*, the K-X association will be facilitated in the mental matrix shared by agent and percipient, and X will consequently emerge in the percipient's mind. In the traditional type of experiment, the agent and percipient are both thinking of the experiment (and doubtless of various other things in common); this idea of the experiment serves as K. The hypothesis is absurdly simple, and is alien to our ingrained assumptions. Yet five large groups of experiments strangely conform to it, in the sense that the closer the associative linkage between the target items and the idea of the experiment, the better the results. In one group of experiments the target items were prepared and listed in advance (thus slightly linked with the experiment but not actually used); in another group they were both *listed* and *drawn* in advance (thus the associative link was stronger); in a third group they were listed, drawn and used

(here the linkage was close). The results in terms of mean scores per percipient per original were as follows:

Class	$10^3 \times \text{Mean D}/\sigma$	P
A. Listed, drawn and used..	21.212	4.67 10^{-8}
B. Listed and drawn, not used	4.332	2.00 .05
C. Listed, not drawn, not used	2.227	1.69 .09
D. Controls206	.16 .87

(3) While Carington's hypothesis is derived from classical association psychology, another, developed by M. P. Reeves (47), takes its departure from field theory of the Lewinian type, utilizing the concepts of tension and of region within the organism. She notes that the motivation or tension impelling to paranormal contact with a given target may lie either in the deeper strata of personality or at the surface. In general, the spontaneous cases express the former situation, the experimental cases the latter. Since tension in one region may inhibit the creation of tension in another, the need to perceive in one way may inhibit the need to perceive in another way; when normal perception is active, paranormal perception is inhibited. But when, through sleep, drugs, etc., the normal effort to perceive is removed, the tensions related to the paranormal may find an outlet. This formulation fits well with the facts available regarding the role of motivation and of dissociation in spontaneous and in experimental telepathy. It can probably be integrated with the Carington thesis if both should appear to be well substantiated by further evidence.

As to philosophical interpretations, almost every form of mind-body theory has been championed, but no one of them can lay claim to any special cogency. Three may be briefly noted: (1) Physical interpretations, as in the various modern elaborations of Sir William Crooke's (11) theory of "brain waves," conveyed from object to percipient, can be stretched so as to make some slight contact with telepathic findings, but the data do not fit the inverse-square law, and a physical interpretation of precognition involves an elaborate *ad hoc* form of speculation. Perhaps the physics of a future period will integrate with the data in a more evident way than does contemporary physics. The physiological aspects of extra-sensory capacities may

have some relevance to this physical question, but they have been studied only slightly. The physiological approach is considerably clarified by the discovery of the stimulating effects of certain drugs and the inhibiting effects of others; e.g., the Groningen study mentioned above showed the great facilitating effect of small doses of alcohol, while Rhine showed the depressant effect of sodium amytal on scoring level and the restorative effect of caffeine.

(2) Dualistic interpretations, positing a mental realm sharply separated from the physical realm, encounter all the usual difficulties, especially in connection with the *modus operandi* of mind-body interactions. And it is to be doubted whether they *explain* the phenomena. But what they do is to make the phenomena less "shocking," bringing them into line with less bizarre experiences in the realm of normal perception.

(3) There is nothing in the data to rule out a completely monistic system, perhaps of the panpsychist type, in which all reality may be regarded as ultimately psychic, and matter a name for specific kinds of experiences referred to the observer's world of space (this is not Berkeleyan idealism; it regards nature as independent of man, being similar to Eddington's "philosophy of physical science" (14).

At this writing, one critical experimental task would appear likely to be very helpful in pointing toward a monistic or dualistic view. It will be recalled that Rhine has stressed the reality of clairvoyance—paranormal perceptual contact with objects as independent from telepathy—a view to which some other scattered evidence points. Clairvoyance appears to call for powers of an order very different from those involved in mind-to-mind contact (whether simply telepathic or in the form of precognitive telepathy). If clairvoyance could be eliminated, it would probably help to prepare the way for a monistic view, involving some sort of panpsychist or double-aspect view. It has several times been suggested that clairvoyance is not in fact well established, since in experiments purporting to test clairvoyance, the subject may make precognitive contact with the experimenter's mind as it will be at the time of the check-up. This argument is not, however, appropriate in relation to the many studies by the matching methods, for example, to the Pratt-Woodruff matching experiment mentioned above, in which the *order*

of cards in the check-up was determined by the subject's order of placing them. Apparatus has recently been devised which will record total hits while never allowing any human mind to know the individual targets; this may perhaps help in studying the question of pure clairvoyance.

There is also considerable evidence for clairvoyance from dowsing—use of the divining rod to discover subterranean water (or minerals, etc.). The dowser holds a forked stick which turns down as he wanders over the ground when water is directly underneath. In a carefully planned experiment, Sir William Barrett (3) tested the well-known dowser William Stone, at Carigoona, Ireland, in a terrain unknown to him and offering no geological clues. The latter promptly found water at several spots. The testimony of geologists regarding the difficulty of the feat is a part of the record. Similarly Sir Henry Harben, who had invested large sums in boring for water under the advice of engineers without success, employed a well-known dowser, John Mullins, who quickly located springs 12 and 19 feet below the surface. There are many records of such feats, but the problem has not been systematically studied. It cannot yet be said categorically that the turning of the rod is solely due to a motor automatism on the part of the dowser, analogous to automatic writing; but there is much to support this view.

PSYCHOKINESIS

Along with paranormal cognitive processes, there have been reports throughout history of paranormal physical effects: lights, raps, movements not appearing to conform to ordinary physical law. The nineteenth century had its numerous cases of Poltergeists ("troublesome spirits")—loud sounds, violent movements of objects, etc., usually in the presence of a pre-adolescent child; and of lights, raps, materializations and levitations in the presence of a spiritualist medium. The reports of D. D. Home's floating through an open window in bright daylight (13), and the movements of a curtain, and kindred unexplained phenomena, in the presence of Eusapia Palladino (17), are typical fragments from a bewildering picture. Much fraud has been detected under loose conditions which permit it; but a very large mass of material remains unexplained. Systematic

and careful experimentation upon such phenomena under acceptable conditions did not, however, begin until the 1930's, when J. B. Rhine and his associates at Duke University embarked upon a program of research on the possibility of mentally influencing the course of physical movements outside of the body—psychokinesis or PK. Because of their mobility and the ease of obtaining with them a statistically meaningful result, dice were used, the subject undertaking to influence their manner of falling after being thrown. As in the case of ESP, rough preliminary studies were followed by more elaborately controlled experiments. In these experiments the dice have been found, under control conditions, to fall in a manner conforming roughly to the expected "chance" distribution; yet when subjects are instructed to endeavor to influence them, such an influence appears in significant form (25, 54, 55, 56). Typically, the instructions in one series are to try for *ones*, in another series for *twos*, etc.; the dice show different "preferences" as different psychological conditions obtain. While the dice are sometime thrown from a cup, various types of mechanical release of the dice have also been used. The following (56) are results with such mechanically thrown dice (a run is twelve throws of two dice each), the effort of the subject being to make the sum of the die-faces 8 or more, and chance expectation being 5.00 per run.

Runs	Average per run	Hits	Dev.	S.D.	CR
108	5.65	610	+70	17.77	3.94

Giving special attention to the problem of mechanical release, Rhine had a rotating cage constructed in which the dice were tumbled about; in the main series with this method (48), the subjects trying for specific die-faces, with chance expectation at 4.00 per run, the results were:

Runs	Average per run	Hits	Dev.	S.D.	CR
44	4.86	214	+38	12.10	3.14

One very striking aspect of the psychokinetic work is that the scores bear a clear relation to the structure of the task, as do ESP scores. In the case of PK, decline curves during each task are clear; but arrival at a new phase of the task, as in starting a *new record sheet*, is accompanied by a renewal of relatively high

scoring (54). These decline effects have been studied in a vast amount of material (over a million die-throws) and are so consistent as to achieve a very high level of significance. Their effect in a typical series (54) is graphically shown in Figure 2, in which the scoring level in each of the four quarters of the *record sheet*, 1, 2, 3, 4, is shown by the heights of the columns.

FIGURE 2

The effect is as clear when the subject aims to influence a large number of dice at once as when a single die is involved, and it is apparently not appreciably linked to the size of the dice—considerations which argue against the operation of any simple physical force of the types now understood. While ESP studies have been repeated in other laboratories, well-controlled work on PK appears to have been done in only a few laboratories.

MEDIUMSHIP

Throughout history, many of those experiencing paranormal impressions (especially apparitions and precognitive dreams) have attributed them to the action of the deceased. Without any prejudgment as to the facts, and with very profound sensitization to the biological difficulties involved in any hypothesis of survival beyond death, it has been one of the tasks of psychical research to pursue and investigate everything that might appear to bear upon this question. Apparitions coinciding with death, as reported above under the heading of spon-

taneous telepathy, are explicable on the assumption that the telepathic activity occurs at or just before death; but it must be noted that a very considerable number of cases qualitatively similar to the death-coincidence cases do occur days or weeks after the moment of death, and that some of them take the form of repeated appearances to the same person or to groups of persons, especially in the physical surroundings in which the deceased once lived. There has been much serious analysis of such cases, to see whether they support the survival hypothesis.

A more direct approach exists, however, to the survival problem. Throughout the Greco-Roman and medieval periods there had been certain individuals through whom came impressions purporting to emanate from the deceased; and with the rise of modern spiritualism in the middle of the nineteenth century, mediumship in this sense became widespread. Sometimes the medium, or mediator between deceased and living, experienced visions or voices in the waking state; sometimes messages purporting to come from the deceased took the form of automatic writing or of full-fledged trance, with loss of consciousness, and with control of the organism by a personality purporting to be a deceased individual. Many thousands of pages of such automatic writing or of trance utterance have been published with detailed analysis of the contents as bearing on the hypothesis that it derives from identifiable deceased persons.

Thus Mrs. A. W. Verrall (78) reported such incidents through Mrs. Thompson when a sitting was held in her (Mrs. Verrall's) home by a Mr. and Mrs. A. It was stated that Mr. A. had a relative, a "rare old lady for knitting"; that this lady used to carry about with her a round knitting-basket which contained her "top-knot, an ornament for her head, a cap you might call it, but it was a top-knot." Mrs. A. was well acquainted with an old relative of Mr. A.'s, who was a great knitter, but had never seen her with a round knitting basket or any cap basket, and knew nothing of a "top-knot." Mr. A. could throw no light on the statement. Mr. A.'s sisters, on hearing the above account, said that the relative in question, having somewhat thin hair in middle life, before adopting the old lady's cap, with which Mrs. A. was familiar, had worn a little knot of black lace on the top of her head which her young relatives called her top-

knot, and which she used to take about with her in a round knitting-basket.

It was also stated that Mr. A.'s mother, being "a clearing-up, methodical lady," possessed a manuscript receipt book, still in existence in her husband's house, and that in this book were receipts other than cookery receipts, and in particular a receipt for pomade, or, as the lady herself used to call it, "pomatum." It was known to Mrs. A. that her mother-in-law had had such a receipt book as described, but nothing of its contents was known to her. The existence of the book was not known to Mr. A. The daughters knew of the book, and said that *pomatum* was certainly the word used by their mother for the article in question. But they knew nothing of any receipt for pomade. The book was found; it had been written in from both ends and was carefully indexed. No receipt for pomade appeared in the index, but a search was made through the book. It was then found that the last five receipts, counting from one end, had not been indexed, and that among these was a receipt for pomade. The book had never, so far as is known, left the house where its owner had lived, and Mrs. Thompson had certainly never entered that house.

The term "evidential" is used with reference to such communications if there is cogent evidence that no normal knowledge of the information could have reached the medium. Attention has especially centered upon instances in which specific personal information known to have been possessed by the deceased is given through the medium to a sitter as evidence of identity, under conditions which preclude the possibility that either of them could have had access to the information. If telepathy be accepted as a fact, we face, of course, a grave complication, in that most items which might serve as evidence of identity will be known either to the sitter or to other living persons; and before survival after death can be regarded as clearly indicated, it must be shown that such information did not emanate from the minds of the living. The problems will be illustrated by reference to the work of two well-known trance mediums.

A young American woman, Mrs. L. E. Piper, had gone to visit a medium and in consequence had fallen into a trance herself, and began to give trance sittings. She became known to William James in 1885, who was impressed by

communications through her to his wife and himself, and her phenomena began to be studied intensively by Dr. Richard Hodgson and by the Society for Psychical Research in London. For some 30 years her trance communications were systematically analyzed, with emphasis upon two classes of material: (1) material known by the sitter but inaccessible to the medium; (2) material unknown to both medium and sitter, but verifiable by subsequent inquiry (cf. 79). An example of the former may be noted in personal details given by "G. P.," a friend of Hodgson, regarding items which he and G. P. had discussed privately (23). As an example of the latter, we may refer to the many communications purporting to come from F. W. H. Myers, a Greek and Latin scholar, who had died in 1901. Mrs. Piper had no classical education at all. Specific questions regarding Greco-Roman mythology and poetry which were addressed on many occasions to the purporting Myers communicator yielded striking results. Thus George B. Dorr held a sitting with Mrs. Piper in Boston in 1908, at the end of which he asked the purporting Myers, "What does the word *Lethe* suggest to you?" (39) The answer, during this and the subsequent sittings, was a complex pattern of Greco-Roman material. "Cave . . . sad—lovely—mate . . . Entwined love . . . a lady . . . a hoop and two pointed things . . . she pulled a string and she pointed it straight at me . . . Second sitting: Iris—Morpheus—CYX . . ." None of which was recognized by the sitter or by the classical group studying the Piper communications; the answer was regarded as a failure. But ultimately the mass of material was found near the end of Ovid's *Metamorphoses*, in connection with a journey to *Lethe*. It is the story of Ceyx and Alcyone. No generally accessible English source, such as Bulfinch's *Age of Fable*, contained the material; and whatever intelligence was communicating appeared to be working from the Latin text, not an English version. The *Lethe* question and answer were communicated to no one outside the S.P.R. group of classicists. Subsequently an envelope was sent by Sir Oliver Lodge to another sensitive, Mrs. Willett, in England; when this was opened she noted the question, "What does the word *Lethe* suggest to you?" The reply in automatic writing was an immediate reference to the fact that this question had been asked before, the name Dorr given, and a

long series of references to the journey to Lethe in Vergil's *Aeneid* (32).

The same general type of phenomena, transcending any explanation in terms of telepathy from sitter to medium, has been extensively studied in the case of an English sensitive, Mrs. Osborne Leonard, with whom research sittings have been held since the end of the first World War. In her case also it has been commonplace to give material unknown to the sitter. Thus Mrs. Hugh Talbott, who states that Mrs. Leonard knew neither her name nor her address, and with whom she never sat before, received from the trance personality ("Fedra") reference to a communicator who wished to identify himself by reference to a dark leather book, containing upon page 12 or 13 a "diagram of languages . . . Indo-European, Aryan, Semitic languages—likewise a table of Arabian languages, Semitic languages"—drawing with the finger lines extending sideways from one center. This made no sense to Mrs. Talbott. But she succeeded in finding a black leather notebook, into which she had never looked, and encountered on page 3 a "Table of Semitic or Syro-Arabian Languages," and "A General Table of Aryan and Indo-European languages" (63, pp. 253-260).

The question of "chance" in such communications is usually regarded as irrelevant (it is hard to see how the conception can be applied in cases like that of the diagram of languages); yet the problem is not hopeless. One may choose a group of sitters unknown to the medium, record messages given to each of them, require each sitter to annotate each item in each record (those of the other sitters as well as his own) as appropriate or inappropriate to his own situation, and apply standard statistics for comparison of genuine hits and "pseudo-hits" (items appropriate for another sitter). In J. G. Pratt's (40) work with Mrs. Eileen Garrett at Duke University, fourteen sitters took turns as sitter, in a room adjoining that of the medium, and not hearing what she said, so that each one, as he scored the record, was unaware which record was intended for him. The results were significant.

CROSS-CORRESPONDENCES

As we noted, F. W. H. Myers died in 1901. Shortly thereafter there began to appear through Mrs. Piper and through several other automat-

ists many Myers-like communications. Frequently an identical or similar message would be given through two widely separated automatists; and there was frequent reference by the communicator, through one automatist, to what had recently happened during sittings for communications through another. At times the communicating intelligence would undertake, either alone or in collaboration with another communicator, to give a complex message through another automatist, as in the "Hope, Star and Browning" episode: On February 11, 1907, the purporting Myers through Mrs. Piper (in the United States) said that he had referred to "Browning . . . Hope and Browning . . . I also said Star . . . look out for Hope, Star and Browning." On the preceding January 23, Mrs. Verrall (in England) had written automatically "rearrange these five letters . . . tears, stare, and on January 28, aster (star) . . . the hope that leaves the earth for the sky —Abt Vogler." Browning's Abt Vogler thus completes the reference. Moreover, when J. G. Piddington went to Boston in 1906 to clear up the matters left in disorder by Hodgson's death, he found among the papers, in Hodgson's writing, stare, tears, aster, etc. Hodgson was one of the group purporting to be helping with this effort at cross-correspondence (38, pp. 59-77).

Many members of the S.P.R. group believed that such communications yielded especially cogent survival evidence, especially because of the rich classical material given appropriately by the purporting Myers; and time may support this view. But since there were many evidences of some sort of telepathic interchange between the members of the group of automatists, and since *some* members of the group possessed considerable classical information, one could, if one wished, extend the hypothesis of "telepathy from the living" to the point of declaring that all the communications, regardless of their form, were of this origin. It was therefore of great interest to note the emergence, in the automatic writing and in other communications, of an evident effort to develop a new method of delivering communications which could not easily be interpreted in this way. The results of the new method came to be called the "cross-correspondences." A cross-correspondence is a coherent message discovered after two or more independent scripts through independent auto-

matists have been studied; no automatist has received the whole message, but the parts, fitted together, make sense. One automatist gives, as it were, a piece of a jig-saw puzzle, a second and a third give other pieces, the integral meaning being discoverable only after the event. Thus Mrs. Verrall in England wrote automatically a description of a painting by Raphael showing Pope Leo prevailing upon Attila to forego the sack of Rome; Mrs. Holland in India wrote "Ave Roma immortalis. How could I make it any clearer without giving her the clue?" (28, pp. 297-303). Frequently a word or phrase is developed in somewhat different directions in the work of two or more automatists; thus two days after Mrs. Verrall had automatically written much Vergilian material emphasizing shadow and umbrae (shadows), and the words "Let Piddington know when you get a message about shadow, Mrs. Holland wrote tenebrae (shades) . . . shadow and light . . . the sundial at Broadmeadows." (38, pp. 222-227).

It has not been possible to achieve by such methods a type of a universally acceptable proof of survival. There is much evidence that the trance consciousness is impelled by the social situation to impersonate deceased persons, and some evidence that the trance consciousness can draw from the minds of other living persons materials essential to the execution of this histrionic task. The difficulties are exemplified in the *Sevens* case (29, pp. 222-263): J. G. Piddington had undertaken to prepare a letter the contents of which he would reveal to no one. The letter contained these words: "If I am a spirit . . . I shall endeavor . . . to transmit . . . the number SEVEN . . . such things as The seven lamps of architecture . . . we are seven. . . . Seven has been a kind of tic with me ever since my early boyhood." The letter was sealed and stored away, so that as a communicator after death he might indicate his identity by reference to its contents. Actually the contents of this intended "posthumous letter," though religiously kept secret, leaked out in telepathic form, and appeared as a very specific cross-correspondence through six different automatists. Through Mrs. Piper came: "We are seven. I said clock! Tick, tick, tick!"; through Mrs. Verrall, "the sevenfold radiance" . . . "we are seven," "many mystic sevens"; through Mrs. Verrall, "the seven hills of Rome"; through

Mrs. Frith, "the mystic seven"; through Mrs. Holland, "there should be seven in accord"; through Mrs. Home, "seventy times seven." Of course it is not stated that this excludes the action of the deceased; indeed, the material is interwoven with Myers material, and is claimed by the purporting Myers as a triumph. Yet we must recognize that "telepathic leaks" of the sort that occurred from Piddington's mind may be going on between all the automatists. If, then, the automatists should all tend, at an unconscious level, to pose as deceased communicators, and if they are in telepathic rapport with one another, final proof of an independent intelligence is hard to devise.

The cross-correspondence method involves, as it were, collaboration among the living. There has also been evidence, as noted, of an intended collaboration among the deceased. The message takes the form of an utterance prepared by two or more communicators; the communicators seem determined to make a statement not derivable from the mind of any one person but intelligible on the hypothesis of a merging of their efforts after death. The best example of such collaboration is the *Ear of Dionysius* (1). Through Mrs. Willett, who was not at all a classicist, came in Mrs. Verrall's presence, this script: ". . . a place where slaves were kept—and Audition belongs, also Acoustics. Think of the Whispering Gally (sic) . . . One Ear, a one-eared place . . . to sail for Syracuse." At a sitting a month later came: "Add one to one One Ear X (sic) one eye . . . entrance to the Cave . . . A Fountain—a trident. Poseidon . . . Chipping . . . it's on stone . . . He was turned into a Fountain that sort of Stephen man . . . they've thought it out together. Father Cam walking arm in arm—with the Canongate . . . a zither . . . a green eyed monster." These items, unrecognized at the time, fell into order upon discovery of the tale of Dionysius, tyrant of Syracuse, who imprisoned his slaves in a stone quarry, alleged to have been a whispering gallery. Here the poet Philoxenus had written a satirical verse, to be recited to the accompaniment of the zither, at the expense of Dionysius, entitled *Cyclops*; in this he represented Dionysius as blind of one eye. The obscure tale had been known to Dr. Verrall, who is represented as communicating. The Aristotelian references which are interwoven with this story are offered as coming from Henry Butcher, a

friend of Verrall's; the two are represented as having contrived the message in collaboration. The excessively recondite materials are apparently to be found together in English only in a book unknown to Mrs. Willett and known only by name to Mrs. Verrall. It is remotely possible that Mrs. Verrall may have been the unwitting source of the *Ear of Dionysius* communication, or that the requisite material was drawn partly from her, partly from other classicists, either in the S.P.R. group or elsewhere. This is, of course, pure speculation. But we are unable to specify just where such telepathy among the living stops, and are therefore unable to specify what type of survival evidence would in fact be convincing.

PROXY SITTINGS

Research on the problem of survival has, however, become more elaborate, and evidence has improved by the development of "proxy sittings" in which the "sitter," who desires to receive communications, is not physically present with the medium. A note-taker conducts the sitting for the distant sitter. Many such studies have been published. C. Drayton Thomas has in many cases acted as note-taker for distant bereaved persons, who have given him a minimum of information about themselves or the desired communicator. In the Newlove case (72), for example, the communicator, purporting to be a boy who has recently died, offers detailed information about himself which was unknown to the note-taker but verifiable by communication with the bereaved, while indeed some of the contents related to incidents in the boy's life of which they themselves were ignorant but upon which information was later collected. Just as in the case of ordinary mediumship, it has been possible to develop mathematical formulae to indicate to what degree the proxy material transcends a chance explanation. The most outstanding result of this type is reported by J. F. Thomas in a volume entitled *Beyond Normal Cognition*, 1937. The formula involves the scoring, as either correct or incorrect, of each item given, and the comparison of hits (statements really appropriate) with pseudo-hits (statements appropriate to some other sitter). Actual results were compared with the results which sheer guessing would give; the hits were of an astronomical order compared with the pseudo-hits.

THE MODUS OPERANDI OF COMMUNICATION

In an attempt to systematize the complex masses of mediumistic data, Richard Hodgson attempted, in his first studies of Mrs. Piper, to treat all communicators simply as secondary personalities of the medium; later, receiving accurate personal communications from his deceased friend G. P. in a manner which to him precluded altogether the possibility of Mrs. Piper's normally acquiring the information, he swung to the view that the trance personalities are in fact the deceased (23). Neither hypothesis seems to do justice to the facts, and Mrs. Henry Sidgwick (62) offered an ingenious alternative hypothesis which time has done much to strengthen. Noting that some sitters received consistently good material, others little or nothing, she undertook to emphasize the role of the sitter in terms of his influence in facilitating the communication of ideas to the medium. In diagrammatic form, one may schematize the communicator as functioning through a subliminal stratum of the sitter's mind, in such fashion that the material reaches the trance consciousness.

Sitter's Supraliminal
Communicator → Sitter's Subliminal → Medium

This is, of course, a theory of telepathy from the deceased. It has the great advantage that the communicators themselves, the entities with whom one talks at the sitting through the medium, may be regarded simply as secondary personalities—a thesis supported by many observations, notably by the evasions, contradictions, and frequently inappropriate behavior and utterances of the personalities. The deceased Richard Hodgson, for example, as purporting to communicate through Mrs. Piper, differs in fundamental respects from Richard Hodgson as known to his research associates. On the other hand, the very large amount of evidential material given by the communicators suggests the possibility that telepathy from the deceased may sift through into the trance utterances. This hypothesis is apparently applicable to Mrs. Leonard and to other mediums as well. But it must be noted that many students of the phenomena believe, in spite of the arguments noted, that some form of actual invasion of the medium's entranced body is effected by the communicators, who struggle, as with a clumsy machine, to make their meaning clear.

The Sidgwick hypothesis regarding telepathy from the deceased may be applied to the proxy cases in such fashion as to suggest that they do not actually alter the theoretical situation. Just as the sitter may act as channel of communication between the deceased and the medium, so the note-taker may act as a channel of communication either from the deceased, or from distant living persons, or both.

Distant Sitter's Note-taker's
Supraliminal Supraliminal
Communicator → Subliminal → Subliminal → Medium

The two Hodgson hypotheses noted and the Sidgwick hypothesis do not by any means exhaust the possibilities; some investigators prefer various other psychological, and indeed various other philosophical possibilities. These cannot be adequately summarized here. Even as to the question of survival itself, data of this order of complexity do not safely lend themselves to any generalization in terms of "sound opinion" or the "consensus of experts." A number of the most competent and seasoned investigators are completely convinced of the reality of post-mortem communication, others completely convinced that paranormal powers of the living are adequate to the task; a large group declines to reach a final judgment on so complex an issue. But no systematic attempt has been made, so far as the writer is aware, to interpret the phenomena without extensive use of some working hypothesis regarding paranormal capacities.

It is, however, a general opinion among those working in the field that the sheer accumulation of more and more evidence of the present types is not likely to solve the problem; they feel that they are working in an obscure area in which there is but limited knowledge of fundamental principles. On this basis it is possible that the larger problems cannot be solved at all except by patient, grubby psychological work on the paranormal powers of the living under well defined conditions, and that, as in the case of physics and biology, sound general principles will emerge only after many decades of patient work by a large number of technically trained investigators. The research on survival continues actively. But as measured by the number of investigations and the amount of research done, the most prominent concern of psychical research today may be said to be (a) the study of those psychological and physiological condi-

tions under which paranormal phenomena, spontaneous or experimental, appear; (b) the devising of special experiments which will give maximum opportunity for these special conditions to manifest themselves; (c) the resulting development of a consistently repeatable technique; (d) the discovery by all these means of the laws or principles underlying the phenomena; (e) the eventual construction of a system of knowledge which will bind these principles together, so that all of the various types of paranormal phenomena will make a meaningful whole, internally coherent and in meaningful and intelligible contact with the general laws of psychology.

PERCEPTION.—Perception always has been a persistent, and I think we may safely say, a central problem of psychology. In the hands of the classical philosophers it took its importance from its bearing on epistemology with the problem of which it was wholly absorbed. With the empiricists and associationists in their attempt to build up knowledge from concrete instances, perception naturally became a principal means of attaining inductive knowledge. Upon the application of the experimental method in psychology, perception came to be studied as of interest for itself. During the period from 1915 to 1940 its systematic importance increased very considerably under the influence of the tendency toward a realistic attitude induced by widespread application of experimental results in the physical sciences.

In 1920 Professor Titchener (1) proposed Perception as the topic of his graduate seminar and introduced the subject as follows: "For some years past it has been plain that the problem of perception is to be the key-problem of a systematic experimental psychology. We have worked, so to say, on either side of perception: we have worked upon sensation and we have worked more recently upon thought. We have an immense amount of valuable detail, a great store of observed facts; but we have no systematic consensus . . . If you reply that perception has never been neglected, I grant the objection, but I maintain that the study of perception hitherto has been a study within a separate chapter of psychology; the connections above and below have been made speculatively but not experimentally. But now perception shows in a new light; it is systematically central; sensation and thought both alike depend upon the outcome of its experimental analysis. More than that: if we can be sure about perceptions, we shall have laid the basis for a psy-

chology of attention; we shall have gained entrance to the psychology of memory and imagination; and we may even hope—by the explication especially of the elementary motives—to get some insight into the psychology of feeling.

"We reach the heart of the problem of perception when we undertake to exhibit the transformation that the sensory basis undergoes in the making of a perceptive complex. It is, I hope, hardly necessary to say that we shall not regard the transformation as a genetic process of temporal development out of sensory material. The perception comes first in time; the sensation is the outcome of our scientific abstraction. What we have to do therefore, is to analyze psychologically the already formed perception, and to explicate the conditions under which the integration of these analytical factors obtains. We begin with the perception. But when we know the analytical components and the relevant conditions, we can work backwards and reconstruct the perception out of its elements; in that way our problem becomes in a certain sense genetic, though the genesis is logical and artificial rather than chronological and natural. Failure to differentiate the two kinds of genesis has been responsible for a vast deal of confusion and for much needless controversy. We do not, to repeat—we do not derive perception in time from an assemblage of sensory attributes; but taking a perception as it occurs, and analyzing it, we hope to be able to test an analysis by a subsequent synthesis; and that is in its way an affair of generation or genesis."

During the same year, psychologists in this country had hardly completed the assimilation of the considerable literature accumulated in Germany during the war of 1914-18. This contained in a new guise an hypothesis that had its beginnings in the "Form Quality" of Meinong and Ehrenfeld. Max Wertheimer (2) published in 1912 his now historic experimental study of the perception of "movement." In it he brought out the fact that not only is the perception of movement not directly dependent upon the physical spatial translation of an object—Plateau had demonstrated that nearly a century before—but that the experience itself does not consist essentially in those aspects logically implied in the significance of the term, namely space, time and identity of an object. Movement can be

perceived, so he asserted, without experiential reference to any of these, as an immediately given phenomenon. Movement is the direct mental correlate of a short circuit in the central nervous system, presumably in the cortex, between the projection areas of two spatially-temporally separate regions in phenomenal space. In an extreme case the short circuit may take place in the absence of activity in the two primary regions of the cortex, i.e., "pure movement" may be apprehended completely independent of a starting or an ending position of an object. Thus "movement" gains the status of an independent, experiential entity, complete and unitary in itself, with a specific, though hypothetical, physiological correlate that reflects in immediate experience the phenomenally given event. Such is the seed from which Gestalt Psychology grew and it contains the fundamental hypotheses that are of interest in our present discussion. (1) A perception is a complete experiential entity—not a composite of simpler experiences and therefore, in that sense, not analyzable. (2) It is the reflection in experience of a similar (but hypothetical) physiological condition. (3) The physiological condition is itself the projection into the sensorium of an entity of the phenomenal world. The task for Gestalt psychology becomes the enumeration of experiential entities together with their correlated phenomena and their centrally projected processes. Being entities, the former need only to be identified. They are the "Gestalten" in terms of which experiences are to be characterized. Following Wertheimer's establishment of the original movement—Gestalt, many others have been discussed. There are, for example, the various manifestations of "constancy" (3, 4, 5). The fact that the apparent color of an object remains the same under wide variations in color and amount of illumination is designated color constancy. Some of the phenomena are what Hering called "memory color." Likewise, through size-constancy objects appear to retain a true magnitude irrespective of distance. Figure-ground relationships of objects and patterns in the visual field have received considerable attention. Reversible perspective, visual illusions of size and direction, etc., have been included under this interpretation and the concept has been extended and modified to include focal perceptions in audition. Several principles or laws of organization (3) have been worked

out, which govern the formation of figures, among which are proximity, similarity, set, closure, goodness. Categories of this sort make up the conceptual terms used in the discussion of perceptions as mental Gestalten.

Here, then, are the two current systematic positions relative to the problems of perception. They cannot be said to be opposing theories because they are in many ways parallel and supplementary. Their systematic influence, however, has very different effects. Within Gestalt psychology, perception furnishes the prototype of all mental structure or organization. Once established it becomes the *a priori* reference point of the system. In a descriptive psychology, perception holds the important position that Titchener indicated, but it is only one schematic, conceptual device, among many, for organizing the data of observation.

In the present discussion, we shall draw from both systematic positions as it suits our purpose. To begin with, we shall take unitariness of perceptual phenomena as axiomatic. All experience that at any moment stands at the higher level of vividness and is reportably clear, is found to constitute a perceptual unit. Aristotle pointed out that only one "idea" could be in mind at a time, but we have learned much since his day about the possible complexity of such "ideas" or perceptions, and about the unstable stage of attention set up when two mutually competitive perceptions or "ideas" are presented by the situation. It should be made clear at this point that the unitariness of which we are speaking is simply a matter of coherence at the level of the operational data found in the course of its enumeration. We cannot comprehend a meaningful unity or a unity of meaning within our definition of the categories of observation. A datum for science is specified by a statement of the operations by which it is obtained. All sciences have their problems presented to them in the first instance by way of gross epistemological phenomena such as "matter," "forces," life," "consciousness," "experience" and the like. A science rarely accepts such concepts as they stand, but performs certain operations upon the phenomena, which yield data that form the basis for new scientific concepts. In practice, a particular set of operations is incorporated in an instrument which is no more than a machine or a system of phenomena that has been calibrated to give sig-

nificant discriminative pointer readings when it is directed at an event of the real world. Take for example, the thermometer. Casual observation noted that felt temperature and apparent volume are related phenomena. Ingenuity devised a simple machine utilizing these phenomena: a liquid, usually mercury, confined in a tube so that every change of volume is transformed into a relatively large linear displacement of the top of the liquid. Finally, calibration gave a precise significance to every position of the indicating column. Two anchor points, viz., the positions of the indicator when the instrument was placed in freezing, and in boiling, water were determined and the thermometric scale defined in terms of them.

The instrument in a psychological experiment is exactly analogous to, though far less simple than, the instrument of the physicist. While we do not have a complete picture of the structure and function of the biological machine, we can calibrate it and obtain from it data that are directly referable to the operations performed. The whole gamut of psychological methodology from Fechnerian psychophysics to factor analysis concerns itself with calibration of the psychological instrument. In any case, the precision of our data is a function of the operations reflected in the calibration. Applied to perception our calibration is in terms of the sensory attributes. These are neither the casual "sensations" of "private experience," nor mental entities, nor simple items of knowledge. They are the discriminative responses or pointer readings of a calibrated instrument. In terms of such data we can write descriptive formulae for perceptions.

However, such a description must not be confused with the phenomenon itself. It cannot give dynamic function, but only content and temporal course and pattern. One would never confuse a descriptive map with the country through which he is traveling, nor would he expect it to reveal the beauties of the countryside, but the map would give him an orientation that he could get in no other way.

Phenomena as we find them are always meaningful and analysis fails to discover a meaning category of the same order as the attributive ones that we have defined. This is the significance of the statement that meaning is prior to the analysis of experience but not intrinsic to that experience. It is not a general-

ized datum but an added interpretation of a particular experience for a given individual. Meaning, therefore, is subject to explication, to statement and restatement in other terms, but not to analysis. To repeat, meaning is prior to analysis. Meaning epitomizes the implications of a complex unit of experience and therefore meanings constitute the labels by which classification of phenomena can be made. In the nature of the case such classification must precede analysis and description, and it is just now that the Gestalt hypothesis has made its greatest contribution to perception. The conventional classification of experiences on a basis of their meanings into sensations, feelings, perceptions and higher mental processes has served us well, but it is obviously outworn. Moreover, though it originated empirically it is just now fundamentally *a priori*. It is this *a priori* classification which the Gestalt hypothesis attacks and for which it proposes to substitute a new classification derived from empirical, sometimes experimental, observation. A reference again to Wertheimer's experiment illustrates this point. According to the earlier empirical interpretation, movement is the spatial-temporal translation of an object and the experience or perception of movement should consist, therefore, in the apprehension of an interrelation of space, time and identity. Wertheimer demonstrates that identity may be lacking, and that space is fixed, in the apprehension of movement under his conditions. Under different conditions other experimenters (6) have shown that apprehension of time may be lacking and that non-visual factors may be introduced—but that is leading us toward analysis. Following Wertheimer's suggestions the Gestalt movement is proceeding with an elaborate, new empirical classification of the meanings or implications of experience, incidentally uncovering many problems for analysis.

We may now consider what the analytic method has to offer. When we direct the psychological instrument upon a circumscribed and controlled set of conditions—a situation—we obtain a report that has two important aspects. First, the data when complete show all the sensory attributes involved in the perceptive unit labeled by a meaning term, which is under examination. Second, the report indicates the mode of interrelation of the attributive aspects. The net result, then, is a structural formula

which is the descriptive equivalent of the perceptual unit and is ordinarily labeled with the meaning term for that perception. It sometimes happens that with the structural formula in hand we can reconstitute the perceptual unit itself. That may, in fact, turn out to be the goal toward which we must work, yet, while a successful synthesis verifies the analysis, its failure betrays a lack of ingenuity rather than an error of observation.

There are three main forms of combination of perceptual units all of which are closely interrelated, so that a particular perceptual experience may include one, two or all three forms.

Primary Integration. When perceptual experiences are brought under conditions of careful observation and are analyzed, particular attributes are found, standing in close relation to one another. Other attributes may be present but may vary without altering the perception. Thus the simplest form of perception consists of a compound or union of two or more sensory attributes into a single unit for experience. This resultant unit has a utility or applicability for the individual that is not present in the elements that constitute it. Frequently it is possible to reverse the analysis and to reconstitute the integration.

The perception of "wetness" (7, 8) offers an excellent example of the simple integrative pattern. First, what does the term "wet" mean? There is no attribute of "wet" in any of the sense departments, though we speak of feeling "wet," of smelling "wet," of seeing "wet," of hearing "wet," and of tasting "wet." This multiplicity of ways of apprehending "wet" is sufficient to indicate that we are referring to some inferred characteristic of an object not to any datum of experience. "Wet" probably means to most people, "the presence of water," though a moment's thought tells us it does not refer exclusively to that substance. We speak also of "wet with blood," "wet with acid," etc. A physical interpretation involves the adhesion of a liquid to a solid. In a specific case we still need to know how "wetness" is experienced, and we must restrict ourselves to one at a time of the various meanings of "wet."

If we examine carefully that aspect of "wetness" which is implied when we say that an object "feels wet to touch," we find that the essential components of the experience are two

qualities, cutaneous pressure and cold. Neither quality by itself feels "wet" and no other quality may be substituted for either. For example, warm water, though practically just as wet as cold water does not give the perception of "wetness." A stimulus which adds the quality pain, or dull pressure will alter the perception. Conversely, the meaning of "wetness" can be set up by any stimulus that brings the two qualities, pressure and cold, simultaneously within the same extent. Thus, if cold, dry powder is allowed to fall gently on the skin, the observer will report "wet." Cooled dry cotton-wool is also felt as "wet"; and the integration takes place even when a pressure spot and an adjacent cold spot are stimulated simultaneously—the former with a horsehair, the latter with a "radiant" cold of carbon dioxide snow. Here we have the integration of two qualities under conditions of identical extent and duration and, of course, with focal vividness. Intensity plays no part in this integration.

In a similar manner the feeling of "oiliness" (9) is an integration of warmth and pressure of a certain extent. As was the case with "wetness," all "oily" substances do not feel "oily" and the perception of "oiliness" can be set up in the absence of oil. Another interesting perception of this type that has been analyzed is "stickiness" (10). This time the integration is of one quality, pressure, and two or more intensities in a particular temporal relation, i.e., a gradual increase in intensity of the pressure followed by a sudden decrease in intensity. Thus the compounding is of quality, intensity and duration. The perception may be synthesized by simply lifting the skin slowly and then releasing it suddenly. This is done either by means of a small tab glued firmly to the skin or by running a thread under a small portion of the scarf-skin. The tab or the thread is pulled gently and then quickly released. Several other cutaneous perceptions have been analyzed. For example, "roughness" (11) is the integration of several punctiform pressures with extent and duration. The stimulating surface must move with respect to the skin surface. The components of "smoothness" are not as obvious, though as contrasted to "roughness" they consist of uniform pressure over the area stimulated.

Visual perception furnishes many examples of primary integrations, some of which have been analyzed. Ordinarily when we deal with

colors we employ colored surfaces of various sorts. It has been shown, however, that colors are not necessarily perceived on surfaces. (12) Surface implies localization and texture, whereas color in its simplest mode of appearance is a film which has no localization and no special texture. Film colors occur in everyday objects such as thick fog, a patch of sky, the color in the eyepiece of a spectroscope. Colors may also appear bulky or transparent, glossy or lustrous but all such object colors can be reduced to film colors by removing the factors that give localization and texture. Unfortunately, the experimental work has not furnished a formula for the modes of color perception comparable with that for wetness, but apparently "film" approaches a single quality while "surface" and "bulk" involve extent and more than one quality.

Most simple geometrical forms (13) are compounds of extent and vividness, sometimes with a qualitative effect. The two lines forming the apex of a triangle are attributively enhanced, and the base line is vague and grayish. The longer parallel sides of a horizontal oblong are described as blacker, clearer, broader and more intense than the shorter sides. The square and the circle are most frequently described as uniform in quality, clearness, extent and intensity in all parts. Certain reversible figure-ground perceptions are integrations of quality and vividness. When the shaded areas are focal the perception is of dark figures on an unfigured background; when the white areas supplant the shading in the focus of vividness the figure-ground perception is reversed.

Core-Context Perceptions. The pattern of the complete typical perception consists of two parts which are logically separable. The data which make up the perception form a single unit, however, and are as closely integrated or combined as those of the primary integration.

Certain of the sensory data in the perception are directly dependent upon the perceptual object and therefore under direct experimental control. Hence they are called the "core" of the perception. Other sensory processes, usually imaginal, which means that they are not directly controlled, accrue to and are compounded with the core to give the complete perception. These are called the context, and this context is the psychological aspect of the meaning. In the absence of a context the meaning disappears

and the perception is incomplete. Alteration of any part is reflected in the whole perception. An excellent example of this type of perception was demonstrated in the attempt to set up the proper conditions for, and to analyze the perception of, "clamminess." (14) Objects which are ordinarily known as "clammy" such as cold boiled potato, cold boiled macaroni, shelled oysters, angleworms and the like were perceived simply as wet or as cold. When, however, an imaginal supplementation was introduced by reading a paragraph in which "clammy" objects were mentioned just before the presentation of the stimulus, these same objects were perceived as "clammy." For example, a thin-walled rubber tube filled with cold, wet sand was laid upon the hand of the observer just after he had been read a paragraph concerning snakes. An image of the snakes gave the meaning of "clamminess" to the feel of the rubber tube. The pressure and cold from the stimulus forms the core of this perception, the images set up by the paragraph make up the context. The total complex means "clammy." The two parts completely interpenetrate and form *one unitary experience*.

Another example from cutaneous experience is the perception by touch of simple geometrical shapes such as the line, the circle, the triangle, the square. (15, 16, 17) The perceptions of these forms by touch are not primary integrations as are the visual perceptions of them. They can be distinguished from one another readily enough by their feel but the geometrical meanings do not proceed from the haptic integrations. The meanings may be added, however, by anything that sets up a visual or verbal image referring to the particular shape. In the same manner, context may be added to any core. Most examples of "tied-images" are perceptions in which the images illustrated form part of the context.

The core-context form of perceptual compound we have called typical because it is the most universally applicable. Only a relatively few perceptions are of the primary integrative sort but any meaning may be carried by a context; any perception characterized by a meaning may be of the core-context pattern. In this form any sensory quality, extent, duration, etc., may stand in the context and give meaning to another quality, etc., but some types of data seem to serve this function more pre-

dominantly. The haptic qualities that come from the muscles, tendons, joints and viscera play a larger part in our perceptions than we usually appreciate. Many objects that occur in various situations require or mean some sort of movement, and our perception of them implies a response whether or not any action is performed. Such meaning is carried in the context of the perception as haptic qualities which often closely resemble those observed in the actual movement.

Implicit Perceptions. Many times when a perception has occurred frequently, it becomes reduced to just those imaged or intended movements mentioned in the preceding paragraph. If you are accustomed to drive a car and chance to be merely a passenger, you continue to push on the brake and pull at the wheel, in short, to drive the car even though you are not in the driver's seat. Thus a great many perceptual experiences appear at first examination to defy psychological analysis. The pattern seems even simpler than in the primary integrations, but the mere combination of the elements presented is not sufficient for the full meaning which attaches to it. We have something that appears to be a perceptual core without a context but fulfilling a meaningful function. Such perceptions always have a long past history in the observer's experience and the meanings are usually expressed in some sort of action or judgment. One turns the proper corners of a familiar street "automatically," one says; one buttons his coat "without thinking"; one judges the rate of an approaching car at a glance. These perceptions have degenerated from the full core-context pattern; the context has dropped out and the meaning is carried by a functional set of the nervous system called a *determining tendency*.

Such implicit perceptions, or direct apprehensions, form part of most of our complex perceptions. They are present, for example, in many judgments of visual size, and direction. In the Müller-Lyer illusion the judgment of the distance from arrow point to arrow point is influenced by the tendency to take each part of the figure as enclosing an area and consequently the two halves of the line appear unequal. The tendency to take all angles as right angles set in three dimensions is the basis for many distorted judgments. The lower end of an oblique line appears tipped up from its true position because

the acute angle is implicitly judged larger, and the obtuse smaller, than each actually is. The upper extension of the oblique is distorted in the opposite direction. The same determining tendency is involved in other "illusions" of direction.

The way in which we take account of illumination in our perception of the colors of objects is so ingrained that it has not yet been traced to its source, but its effect has been demonstrated and measured under many conditions. The phenomenon has been called "memory color" and "color constancy" because when an object is shown under a colored light it will not appear colored in the way that a physical examination would lead us to expect, but will tend to maintain its known color quality independent of the illumination at the moment. If, for example, we set up two gray discs alongside of one another but so screened that one is lighted by daylight and the other by the light from a red electric bulb, we can compensate for the red from the bulb by adding red to the other gray disc and so bring the two to a match. However, if we first set up a screen with two small holes in it so that the observer can see only a small patch of each color and ask him to match the two colors, then when we remove the screen so that he can see the whole arrangement, though the color reflected from each disc is the same in both cases, the one with the red illumination will not appear nearly as red as the one which matched it in daylight when the reducing screen was in front of both. In a similar manner, we neglect the effect of shadows to such an extent that a white paper in shadow is still seen as white though the light reflected from it is less than that reflected from black paper in good light. Many such implicit factors enter into most of our perceptions.

Complex Perceptions. By far the majority of perceptions at one time or another involve all of the forms of perceptual patterning. Perceptions are derived in the first place from everyday phenomena and are named for their meanings or uses without reference to their psychological aspects, their data and their patterns. When we undertake the study of a perception designated by a meaning name, we have before us a problem that requires examination from many angles. Several perceptions have been subjected to such extensive experimental inves-

tigation. Among them is the visual perception of the third dimension.

Visual Space. Space is so general a form of interpretation that there is a strong tendency to put all of our experiences into it. Many times it seems to be an elementary datum on a par with the color quality red, or the tone quality C. Yet when we check this immediacy of space, we find it so variable from time to time under the same conditions that we realize its interpretive character. If you live within visible distance of a mountain range, you note that its apparent distance shifts from day to day. On the other hand, one knows that a moving picture is projected on a flat surface, yet one cannot help "seeing" the persons and objects as solid and as moving from near to far, or the reverse, as well as across the flat surface of the screen. Successive investigators have sought to determine the fundamental basis of visual depth. None has succeeded, but each has contributed to our knowledge of the great complexity of factors involved. We may group these factors under five heads.

(1) First we must take into account certain biological characteristics of the perceiving organism. While the sensory surface, the retina of the eye, is limited to the two dimensions, height and breadth, the organism is capable of almost unlimited movement in three dimensions. One may turn about so that depth or distance replaces height or breadth on the retina, or one can move forward into the dimension which is not directly presented in experience. It is on the basis of these characteristics of the organism that the meaning of depth has been built up.

(2) The meaning of depth or distance may be carried by certain implicit cues. Some of these are:

(a) *Size.* The larger representation of an object appears nearer than a smaller representation. In cases where several objects are involved this factor becomes linear perspective. (b) *Interposition.* If one object partially obscures another it is nearer than the second. (c) *Aerial Perspective.* The outlines of the nearer of two objects are sharper than those of the farther. Use is made of this in stage settings where successive curtains of netting hang in front of the back drop and give increasing depth to the stage. (d) *Light and Shade.* Light is taken implicitly as coming

from above and usually from the right. Thus the high-light on a convex surface is toward the upper right, on a concave surface at the lower left. Often the protuberances and indentations shown in a photograph can be reversed by simply inverting the picture. (e) Movement. Far objects appear to move in the same direction with the observer; near objects, in the opposite direction. (f) Fixation. Fixated objects appear nearer than peripheral objects.

These cues are deeply ingrained implicit perceptions, and are sufficient of themselves to give an adequate apprehension of nearness and farness to objects. It is largely on them that solidity in pictorial art is dependent. Because of their immediacy, most persons have no difficulty in seeing moving pictures in three dimensions. All of them can, of course, be represented on a two-dimensional surface.

(3) The third factor in the perception of depth stands on the border line between a core-context pattern and an implicit perception. The musculature by which the two eyes are directed and adjusted so that both "see" the same object in sharpest detail sets up haptic excitations in so doing, which integrate with the visual excitations. Sometimes we "feel" these excitations as haptic qualities and as such they form a part of the context which gives the meaning of distance. Usually they are not felt, but the distance, for example, of an approaching tennis ball, is judged implicitly, from the shifting of the relative positions of the two eyes. The data which come from pointing the two eyes at the same object are known as the sensations of convergence; those from the focusing of each eye, the sensations of accommodation. (18) Many investigations of this aspect of the perception of depth have been made and these factors have been found to be very accurate and so fundamental that they are present in almost every perception that involves the third dimension, though usually in their implicit form.

(4) The dual nature of the visual organ assists in giving the meaning of distance in yet another way. The two eyes, being set some six to eight centimeters apart in space, "see" two different pictures. The eyes are a part, however, of a unitary visual mechanism which has only a single visual field. The result is that all objects in that visual field should be seen as double except those at the exact distance of fixation. This doubtless is not perceived, how-

ever, as doubleness or as confusion, but integrates into depth. The greater the doubling the greater the distance from the plane of fixation, either farther from or nearer to the observer. It is easy to break up this integration and to see double images of objects not at the fixation distance. If one holds a pencil at arm's length before him, and another about 20 cm. from his nose, either pencil can be seen as double simply by fixating the other.

If perception of solidity depends upon doubleness of vision, it should be possible to present a different flat picture to each eye and to see as a result a single solid picture. (19) So simple and easy is this synthesis that every parlor of two generations ago had its stereoscope and set of slides. The original form of the instrument consists of two small mirrors set at right angles to each other, and two slide carriers. The apex formed by the mirrors faces the observer so that each eye looks into a mirror and sees one of the slides. If these are the two views of a cube seen with either eye, the observer will see a solid, three-dimensional cube. With a little modification this form of stereoscope can be made into a telestereoscope which enhances the apparent distance, or a pseudoscope which inverts the distance of the objects. Substitute a pair of mirrors for the slide carriers and set them parallel with the eyepiece mirrors. In them the objects before the observer appear as they would if his eyes were much farther apart in his head. The perceptual effect is of greater solidity or a model-like appearance. The mirrors can be arranged, also, so that the right eye gets a picture from the left and the left eye from the right. Then objects tend to turn inside out. The same optical results can be obtained by means of prisms and lenses.

(5) When all other bases for the meaning of depth have been eliminated there still remains the filmy appearance of visual qualities which may enter into integrations and give the meaning of depth. Vividness seems to be the other principal attribute in these integrations. Under the simplest conditions they give the perception known as "glassiness" (20, 21) which appears like a section of three dimensional space lying between objects but not necessarily including them. Some of the "impressionistic" painters have succeeded in representing this effect on canvas. It is characteristic of perceptions with a stereoscope but it may be observed by itself

in empty space when the proper conditions of fixation and attention are obtained.

(6) Finally, as the natural outcome of the biological situation mentioned first and of the various perceptual combinations, a tri-dimensional attitude or determining tendency has been so firmly ingrained in the nervous system that the meaning of depth is pre-supposed in every visual perception, and in the absence of the usual depth factors the meaning may be carried by any context which fits the particular case.

Visual Movement. (2, 22, 23, 24, 6) If a person is asked to tell what he sees when an object moves, he will probably say that he sees the object in the course of its changing from one place to another. Logically, movement implies two positions in space and a continuous transition between them. A century ago it was discovered that movement could be simulated with a series of stationary pictures. A picture of an object was presented for a brief interval. There followed a short blank interval and then the object was shown again in a new position adjacent to the first, and so on, alternating blank interval with new position. The proper sequence was obtained first with a machine called a "wheel of life" and later a stroboscope. It consists of a disc with a number of radial slits rotated in front of a mirror. On the side of the disc facing the mirror are drawn the several pictures, one position for every slit. When an observer looks through a slit into the mirror, he sees the reflection of one position of the object. As the disc rotates this is cut off, he sees only the disc for a moment, then the next slit moves into view and he sees the next position of the object. The device, obviously is a rudimentary type of moving picture machine.

When, in order to make the situation simple enough to be observed adequately, the objects are reduced to two lines in different positions, the movement seen between the objects consists of a flash of gray. (22, 25) This simplest type of movement perception is an integration of gray and brief duration. Contrary to previous supposition, extent remains constant and is not involved in the integration. The source of the gray is the projection, upon the background of the lines, of the central gray which is always seen in the absence of, or mingled with, all colors but which appears by itself under special

conditions. The integration is of a simple form but since under these conditions the quality is projected upon the field and not derived from the stimulus, the perception falls upon the border line of the next higher category (core-context). With a physically moving stimulus the gray is supplied by a weak positive after-image set up by the moving object. The psychological data under the two sets of conditions, i.e., physical movement and two stationary positions, are so nearly identical that an observer can scarcely distinguish between them. (26) When he does so it is in terms of speed and regularity of the movement. The successive stimuli give a better perception of movement than does the physically moving one.

Although perception of movement can be reduced to a primary integration, under some circumstances this meaning is carried by a context. In the course of some of the investigations of movement, observers reported that while they did not "see movement" the perception "meant movement," and this meaning was carried largely in verbal-motor or other haptic sensations. That is, they felt themselves saying, "There, there," or they felt or imaged a movement of a hand or foot, or of the whole body. These sensations or images "made the lines seem to move."

Finally, the meaning movement may be implicit in the stationary representation of an object. The relation of streaking lines to visual perception of actual movement by a primary integration is obvious and although these figures cannot be said to give a perception of movement they do imply or mean movement.

Time. The concept of time is simpler in many respects than its mental representation. Whereas time for physics is always past or future with the present only an infinitesimal dividing line between them, in experience it appears either as time going on, the present, or as time past. The mental present is but another aspect of the focus of attention. "Now" may be said to include all data that are at maximum vividness and to last as long as that vividness. When they are replaced by other data they become "then."

The perception of short intervals of time (27) is dependent in some degree upon the length of the mental present. An observer is presented two time intervals marked off by three short sounds (three flashes of light, or three touches),

from one-half second to three or four seconds apart. He is asked to state whether the interval between one and two is the same as, or different from, that between two and three. His judgments are most accurate when the intervals are about one second long. When the first interval is shorter than this he overestimates it or judges it too long, when it is longer than one second he underestimates it. Apparently, what he does is to stretch it or clip it to fit into a single mental present. His region of greatest accuracy gives a fair measure of his mental present, and this we see agrees closely with the normal duration of attention, i.e., about one second.

Just as the duration of attention may be lengthened considerably under certain conditions, so also does the length of "Now" depend upon the perceptual pattern. If a continuous tone is compared with two spaced clicks the former is underestimated; the latter "empty time" seems longer than the "filled time." When the observers describe the two perceptual patterns, however, it turns out that neither time is "empty." Each temporal perception is an integration of protensity with quality. In the one case the quality is tonal, in the other case it consists of haptic qualities from the viscera and muscles. The greater variety of the latter may possibly account for the longer perceived duration of that interval.

The same sort of thing happens with extended intervals of time. During a period in which a variety of perceptual situations succeed each other rapidly, the protensity integration does not take place readily, if at all, and time seems to be going rapidly. One is scarcely aware of the passage of time. Only events are happening. If the perceptual situation remains fairly unchanging for the same length of time, the haptic protensity-quality integration arises in the absence of other data and one experiences time as progressing slowly. The hour of sight-seeing in a busy street seems much shorter than the hour spent in a way-station waiting for a train. However, when we look back upon the past and make a temporal judgment about it, the perceptual estimation is reversed. The meaning of time is carried now by an imaginal context and the judgment will be determined by the variety of data that enter into this context. The events which went quickly in the first case form the basis for an *a posteriori* judgment of the time in which they took place; whereas the

temporal perception of the long wait is retained scarcely at all.

Magnitude. (28, 29, 30) Perceptions of size and intensity play an important role in our everyday experience. In addition, the example of the dominance of mensuration in the physical sciences has led to an emphasis of that field in psychology which has produced the specialized branch known as psychophysics and the elaborate application of statistical procedures.

Intensity or magnitude is a concept, a meaning like time and space, and there is no single perceptual group that is exclusively peculiar to it. Under carefully controlled experimental conditions magnitude may take the form of a simple integration in which intensity is primary; for example, in the comparison of two simple tones. If two vibration frequencies differing only in amplitude are sounded in quick succession, a simple integration of protensity and intensity is set up for a trained observer in the form of an "intensive step" perception. In other situations intensity judgments are based upon the integrations of groups of qualities. The difference in magnitude between two weights is judged from the two simple integrations of haptic qualities from the skin and muscles involved in lifting them. The judgment of the length of a line is a somewhat more complex perception that may be of the core-context pattern. It consists of a simple integration of quality and extent to which sensations from eye movements add a context. All such patterns are closely correlated with the magnitude of the stimulus. However, the tendency of observers to judge magnitudes on the bases of contexts that have no relation to the degree of the stimulus is the source of the greatest difficulties in such experiments. Unless they are carefully trained, observers will compare the intensities of tones in terms of a context of the clicks made by turning the tones on and off, or the visual images associated with the tones. They will perceive a weight as heavier from its size, from its color, or from the sound made in setting it down. They will judge the length of lines from tiny marks or smudges on the background. This illustrates again the versatility of the core-context pattern of perception.

While there is no single pattern for all perceptions of magnitude the quantitative results of psychophysics indicate a constant type of relation between the degree of a stimulus and

the perception it sets up, and suggests a fundamental similarity among all perceptions of magnitude. Whenever you wish to increase a perceived magnitude by a given amount it is necessary to add to the stimulus a certain proportion of that stimulus. The absolute amount added will be greater, the larger the stimulus is, with which you begin. If one light is on in a dark room, a second light will not necessarily double the brilliance of the illumination. The addition to a light stimulus of $1/60$ of itself gives a just noticeable increase of its magnitude so that, if the original stimulus is of 6 candle power, the addition of .1 candle power will be perceptible, but to produce a noticeable increase from a light of 60 c.p. requires the addition of 1 c.p., ten times as much. This explains why stars are not visible in the daytime sky. Sound intensities require a much larger proportion of change, that is, the absolute power (Watts/cm²) must be increased by .75 of itself to be heard as louder. (31)

This law was first discovered in the field of haptics by a German physiologist, E. H. Weber, and named for him by Fechner who extended the observations to the perception of lifted weights and formulated the law as the logarithmic equation $S = k \log R$, in which S stands for the perceived magnitude, k a constant peculiar to the perception and R the degree of the stimulus. Since then some form of Weber's Law has been shown to hold in practically all perceptions of magnitude. Originally the investigators assumed that they were making direct measurements of attributive intensity, but it is recognized now that the perceptions from which the judgments proceed are more complex and that the measurements bear a relation to intensity, similar to that between the range of attention and the range of report.

PERFORMANCE TESTS.—Performance tests might be any tests requiring overt response. In practice, they have come to mean tests which can be given without the use of language, either oral or written, or abstract symbols such as words or numbers by either the subject or the examiner. A *performance scale* is a battery of performance tests, the scores of which can be combined in such a way as to yield a total score that can be translated into an I.Q. or a Percentile Rank, or a Personal Constant or some other index of brightness.

The development of performance tests and performance scales has been stimulated largely by the felt need of some means of measuring ability independent of language by those working with the deaf, with the foreign born, with the individual handicapped by speech defect, and with the individual from a cultural background so different from that of the groups against which the Binet scales were standardized that the Binet scales could be used only to measure his level of attainment rather than his ability. In addition to these uses, performance scales are being utilized increasingly at the present time to give balance to the ratings of verbalistic subjects who tend to rate high on the Binet and other scales involving a large amount of informational material, but have difficulty in achieving according to the predictions based on such ratings.

The early attempts to measure brightness by means of psychophysical tests of sensory capacity aimed at obtaining a measure of native ability relatively unaffected by culture. Elaborate apparatus, procedures involving verbal instructions in some cases rather elaborate, and lack of adequate criteria of brightness combined to produce results that convinced psychologists that brightness or "intelligence" could be measured more adequately by means of a different approach.

Spearman, however, in 1904, (1) with improved methods for the calculation of correlations and by the use of more factors for the determination of general intelligence, found large correlations with general intelligence for discrimination of grays, and weight, and pitch.

Norsworthy's (2) use of the Seguin form board as a test instrument, reported in 1906, represented a different approach to the problem of the measurement of mental ability with non-verbal and non-arithmetic material. Goddard (3) made some important changes in the arrangement of this form board. Twitmeyer made still further changes. It was the Twitmeyer modification of the Seguin form board that Sylvester (4) used in his standardization.

In 1911, Healy and Fernald (5) published a battery of tests, some verbal and some non-verbal, including picture puzzles and form boards.

Knox, (6) in 1914, reported A Scale Based on the Work at Ellis Island for Estimating Mental Defect. This scale included many verbal elements but also included the Knox Cube Test, which later was expanded and standardized by Pintner. (7) Also included in the Knox scale were several form boards. At about this time many other tests of the form board type were coming into use.

Healy, (8) in 1914, reported a Pictorial Completion Test. This differs from the form board type of test in that any one of 50 blocks will fit into any one of 10 apertures cut in a brightly colored picture. The task is to discover the relationships portrayed in the picture, and to find the block for each aperture that will best complete the situation portrayed. This test was so successful that it was followed in 1921 by the Healy Pictorial Completion Test II. (9) Scores obtained with these tests appear to correlate with language ability more closely than many of the other non-verbal tests. It is interesting that in A Manual of Individual Mental Tests and Testing in 1927 by Bronner, Healy and Lowe, (10) these pictorial completion tests are classified under "Language and Ideational Tests." These tests can be given without the use of verbal instructions, but reflect the culture of the group in which they originate to a degree that renders them of little value for use in groups that differ widely from the standardization group in cultural background. (11)

In 1915, Porteus (12) published the first de-

scription of work with his maze tests. The Vineland Revision (13) was published in 1919, and the New Series of the Porteus Maze Tests (14) appeared in 1933. In 1942 Porteus published a report on Qualitative Performance in the Maze Test (15) that indicates the usefulness of performance tests for the observation of behavior under standardized conditions.

Kent, in 1916, published (a) A Graded Series of Geometrical Puzzles (16) and (b) A Graded Series of Picture Puzzles (17).

Wallin, (18) in 1916, in his work with the Seguin form board, made use of "half-yearly" norms up to the age of 8 years. He used year norms above the 8 year level.

The Army Performance Scale, (19) 1921, was "designed during the World War (1) to test foreigners, illiterates and those who had failed on the Alpha and Beta examinations." A correlation coefficient of .84 was found to obtain between performance ratings and Stanford-Binet mental ages.

It should be noted that reports using correlations between mental ages quote values considerably higher than those in which correlations between I.Q.s are presented.

A report on the Ferguson (20) form boards was published in 1920. Although verbal instructions were used, it was stated that the form boards could be presented without the use of language.

The first report of the Kohs Block Design Test (21) was published in 1920. A more complete report came out in 1923. (22) The correlation with Stanford-Binet mental age for 366 cases was $.82 \pm .01$. In the Point Scale of Performance Tests, (23) the Kohs Block Design Test showed the highest discriminative value between successive chronological age groups from 5.5 to 15.5 years, inclusive, of any test of the scale except the Seguin form board. Modifications of this test have been used in several of the more recent non-verbal scales.

The popularity of form boards during this period, made it almost inevitable that A Scale of Performance Tests by Pintner and Paterson, (24) 1917-1923, would be overloaded with form board material. This "scale" is not useful as a scale because of (1) the selection of tests to be standardized, (2) the lack of a satisfactory means of combining scores from the separate tests in such a way as to provide a logical method of extrapolation above and below the

limits set by the year norms, and (3) the double weight given to many of the poorer tests by counting the time score and the error score as separate items in computing the average mental age, the median mental age, the arbitrary point score or the percentile rank. Thus, a maximum of 58 points could be earned on the Two-figure form board, which gives evidence of possessing rather low discriminative value between successive chronological age groups, while only 30 points could be earned on the Seguin form board or the Healy Pictorial Completion Test I, both of which have demonstrated high discriminative value.

The Pintner and Paterson Scale of Performance Tests did, however, emphasize the fact that although many non-verbal tests had been scaled, no scale of performance tests had been standardized as a scale prior to its appearance. It also re-stated the principle that "the chronological age of the child is the measure of our test." (25) It might be added that chronological age still remains the only objective criterion of native intelligence from infancy to adulthood. The Pintner and Paterson Scale of Performance Tests is still useful as a handbook for the 15 non-verbal tests that it reports.

Another approach was made to non-verbal testing in 1926, by Goodenough in "The Measurement of Intelligence by Drawings." (26) Verbal instructions have been used for this "Draw-a-man" test. For non-English speaking children, instructions have been given through an interpreter. (27) For use with deaf children, norms are needed for drawings obtained without the use of verbal instructions. For chronological age groups 4 years to 10 years, inclusive, a correlation of .76 with Stanford-Binet ratings is reported.

In 1928, Drever and Collins published their Performance Tests of Intelligence (28) designed especially for use with deaf children. In 1936 a second edition appeared. (29)

In 1930 A Point Scale of Performance Tests (30) by Arthur was published. Form I of the scale had been standardized against a population of average American school children: approximately 100 at each chronological age level from 5 years to 15 years, inclusive. Form II had been standardized upon only 535 cases and was less reliable. Form I is one of the first scales reported on which deaf children are able to earn ratings comparable to those earned by hearing
